  - Applying external and medially directed pressure on the ipsilateral neck at the level of the thyrohyoid membrane may increase the success rate in difficult insertions. This maneuver collapses the piriform sinus and further clears the way for the nasogastric tube. If the tube passes to the level of the hypopharynx but then meets resistance, grasping the thyroid cartilage and lifting it anteriorly and upward may facilitate passage into the upper esophagus.
  - Orotracheally intubated patients often present the most difficult challenge for inserting a nasogastric tube. If nasogastric insertion is deemed impossible, a second endotracheal tube may facilitate orogastric tube placement. Remove the respiratory adapter from the proximal end of the second endotracheal tube, lubricate it liberally, and insert it through the patient's mouth and into the esophagus. A well-lubricated nasogastric tube can then be inserted through the second endotracheal tube, which can then be removed over the proximal end of the nasogastric tube.

- Nasogastric placement may be facilitated manually through the oropharynx with three fingers, if necessary. However, unless the patient is unconscious or paralyzed, a bite block should be in place for this maneuver to prevent the clinician from being bitten.
- In difficult cases, a laryngoscope may be helpful for guiding or confirming proper placement.
- Fluoroscopic or endoscopic assistance may be necessary.
- 11. Confirm the location of the tip as soon as possible after the tube is passed. Ask the patient to speak after placement. If he or she is unable to speak, the tube is in the trachea and should be withdrawn. (Be aware that cases have been reported in which the patient could talk despite tracheal placement of a smallbore feeding tube.) Otherwise, the position of the tip should be confirmed by a chest radiograph. In addition, there are two traditional methods for confirming proper nasogastric placement: checking for absence of rhythmic airflow and auscultating for gastric bubbling when air is injected into the stomach. As it turns out, both of these techniques have been found to be inaccurate and therefore they are not recommended. Even if the tip of the tube is located in the esophagus, duodenum, jejunum, pleural space, or respiratory tract, a bubbling sound may be heard. If proper location is misdiagnosed, the instillation of feeds or air has been reported to result in a pneumonia or pneumothorax with a high chance of an adverse outcome. Fortunately, placement can also be confirmed by aspiration (to check for gastric contents) and by ultrasonography.

NOTE: If gastric juices are aspirated, correct placement has been demonstrated. Testing the pH of the aspirate will further verify placement. We recommend pH indicator strips with 0.5 gradations or paper with a range of 0 to 6 or 1 to 11. It is important that the resulting color change on any indicator strip or paper is easily distinguishable, particularly between the pH 5 to 6 range. The old type of litmus paper should not be used. Rakel and colleagues (1994) reviewed several studies regarding the significance of the pH value of the aspirate. They found that gastric fluid should have a pH of 0 to 4. If the patient is on antacids, histamine type 2 inhibitors, or proton pump inhibitors, the pH is between 0 and 6 approximately 70% to 80% of the time. Fluid aspirated from the duodenum averaged a pH of 6.5. Fluid aspirated from tracheobronchial secretions ranged from pH 6.74 to 8.79. In other words, suspect that fluid from the respiratory tract has been aspirated when the pH is greater than 6.

Neumann and colleagues (1995) concluded that when the pH of the nasogastric tube aspirate is less than 4.0, radiographs are not needed to confirm tube placement. In 2005, the National Patient Safety Agency in the United Kingdom recommended the use of a pH value of less than 5.5 for tube placement confirmation; they concluded a pH value of less than 4.0 (as recommended by Neumann and associates) is too low to evaluate patients practically. If the pH is greater than 5.5, a chest radiograph, still the gold standard, is required to confirm tube placement (Fig. 203-7). However, it chest radiography adds cost and prolongs waiting time before use (it can take up to 8 hours to receive notification from the radiologist). It also increases radiation exposure. There are also case reports of inaccurate confirmations by radiographs, with the tube being located in the midline after perforating the esophagus, subclavian vein, or atrium of the heart.

Recently, the bedside sonographic examination performed by experienced clinicians has been reported to be a sensitive method for confirming the position of nasogastric tubes. It is faster than conventional radiography and can easily be taught to nonradiologists. Confirmation must be done on all small-bore nasogastric or nasoenteric tubes used for feeding purposes before starting feeding to avoid massive aspiration. The distal

CAUTION: If there is ANY query about position and/or the clarity of the color change on the pH strip, particularly between ranges 5 and 6, then feeding should not commence.

Figure 203-7 Algorithm to confirm the correct position of nasogastric feeding tubes in adults. (From the National Patient Safety Agency [NPSA]: Reducing the harm caused by misplaced nasogastric feeding tubes: Interim advice for healthcare staff—February 2005: How to confirm the correct position of nasogastric feeding tubes in infants, children and adults. Available at www.nrls.npsa.nhs.uk/resources/!EntryId45=59794.)

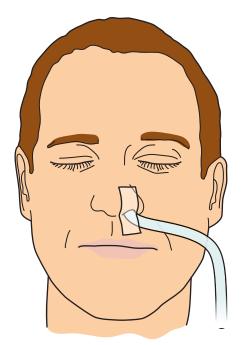

tips of these tubes should be allowed to migrate to the duodenum before enteral feeding is initiated.

- 12. Secure the tube to the patient's nose after confirmation of proper placement. First, apply alcohol to the dorsum of the nose. If available, tincture of benzoin may then be applied after the alcohol dries. Next, obtain a 5-inch piece of 1-inch-wide hypoallergenic tape. Make a 3-inch cut lengthwise in the middle, thereby forming two narrow strips of tape at one end of the 5-inch piece (Fig. 203-8). The two narrow strips of tape should be applied in a spiral down and around the nasogastric tube, going away from the patient's nose. Attempt to tape the tube so that it will rest in the middle of the nostril to minimize direct contact of the tube with the skin of the nose and avoid pressure necrosis. Recently, several commercial products, NG Strip (Cardinal Health, Dublin, Ohio) and TubeGuard (Mormac TubeGuard, North Loup, Neb), have been developed for this special purpose.
- 13. Also secure the nasogastric tube to the patient's gown. Place a slipknot over the tube with a rubber band, and then pin it to the patient's gown. This should reduce the risk of the nasogastric tube being tugged out of position. The Salem sump tube vent, or blue pigtail, must remain above the patient's waistline

- at all times to prevent gravity from siphoning fluid. Inadvertent siphoning of gastric contents could block the sump vent. When suction is discontinued during ambulation, the pigtail should be attached to the connector of the main lumen to close the system and avoid the spillage of gastric fluids.
- 14. For removal, again place the patient in the sitting (Fowler) position and cover his or her neck and chest with towels, surgical Chux, or other drapes. Disconnect the nasogastric tube from the patient, from his or her nose, and from suction. Hand the patient an emesis basin and some tissues. Fold over the proximal end of the tube to prevent leakage and hold it tightly. Ask the patient to flex the neck, breath in, and hold his or her breath. Place a drape around the tube and withdraw the tube from the patient's nose through the drape. The patient can then resume breathing. Discard the tube and the drape.

## **COMPLICATIONS**

The most common complication is discomfort of the patient. The traumatic insertion of a nasogastric tube can cause epistaxis, but this is often avoided by using careful technique and a decongestant.

**Figure 203-8** Secure the tube with a 5-inch piece of I-inch-wide hypoal-lergenic tape, partially cut lengthwise. Apply to the dorsum of the nose and spiral the cut portions down the tube away from the nose.

Epistaxis can be massive and requires packing. It can even compromise the airway. Gagging can occur and induce vomiting with aspiration of gastric contents. This can cause an aspiration pneumonitis or pneumonia with a mortality rate as high as 30%. Patients with an altered mental status from severe trauma or other causes should have their airway secured with an endotracheal tube before placement of a nasogastric tube.

Another common complication is misplacement into the respiratory tree, which is estimated to occur in 15% of cases. This should be recognized rapidly in the conscious patient when it causes him or her to cough, choke, or develop respiratory distress or an inability to talk. The vocal cords may also be traumatized. In a patient with decreased consciousness, tracheal intubation can go undetected, creating multiple complications such as atelectasis, pulmonary edema, pneumonia, or lung abscess.

The "nasogastric tube syndrome" is a reported life-threatening complication with laryngeal and upper airway obstruction and vocal cord abduction paralysis. The nasogastric tube syndrome results from postcricoid ulceration and its effect on the posterior cricoarytenoid muscles. This can be prevented by early recognition and by checking the patient every day when making rounds. It is treated with emergent tracheostomy, immediate removal of the nasogastric tube, and administration of systemic antibiotics.

Penetration of a nasogastric tube into the pleural space is a rare but reported complication, with further possible complications including lung abscess, pneumothorax, isocalothorax, empyema, and sepsis. Intravascular penetration of the internal jugular and subclavian vessels has also been reported.

Perforation of the esophagus is a very serious reported complication that often results in mediastinitis, with a mortality rate of up to 30%. This may occur when the esophagus has been damaged by chemical burns, esophageal cancer, and multiple attempts, or if strictures are present, or with insertion after esophageal surgery. Prompt recognition of this complication, surgical repair, and parenteral antibiotics can significantly reduce the mortality rate. Bleeding from esophageal varices is not usually caused by nasogastric intubation. Duodenal perforation has also been reported. Tube knotting, coiling, kinking, obstruction, and rupture can occur.

With long-term use, sinusitis, erosion of nasal tissue, or even a tracheoesophageal fistula can occur. Tracheoesophageal fistulas are usually associated with simultaneous use of an endotracheal tube. Sinusitis can cause a fever of unknown origin in patients.

If the tube is forced against resistance, cribriform plate fracture may result, with subsequent intracranial intubation. Individuals with mid-facial or maxillofacial trauma or a basilar skull fracture have a significantly increased risk of inadvertent intracranial intubation. The risk of this complication can be reduced by using the orogastric route or by initially introducing a nasotracheal tube or a soft rubber nasal airway, through which a smaller-diameter nasogastric tube can then be passed. This technique decreases the danger of penetrating the cranium, reduces discomfort during insertion, decreases epistaxis, and decreases the frequency of the nasogastric tube kinking into the mouth. The long-term use of nasoenteric tube feeding may result in diarrhea, infection, electrolyte imbalance, and malnutrition.

#### POSTPROCEDURE MANAGEMENT

The nares should be assessed for skin irritation, erosion, or necrosis by health providers at regular intervals. The patient should be asked if he or she has any pain or pressure in the nose, throat, or sinuses. Any old or detached tape should be replaced after cleaning the skin of the nose with alcohol and applying tincture of benzoin. On a regular basis, the nursing team should record the patency of the tube, the level of graduated marks on the tube, any symptoms or patient complaints, the volume and nature of anything infused, and any residual volume. If it becomes difficult to aspirate from the tube, it should be flushed with 30 mL water. If patency is still uncertain, it should be repositioned by advancing 1 inch or withdrawing 1 inch. The same maneuver should then be tried again to confirm patency. Because the use of acidic substances for flushing can cause wholeprotein formulas to coagulate and clog the tube, this practice should be discouraged. The tube should be flushed before and after each intermittent feeding, after medication administration, or every 4 to 6 hours in case of continuous infusion. When the volume of residual is higher than 300 to 400 mL or there is significant gastric distention, the clinician should be notified and any infusions held. Infusions should be held for several hours and the residual rechecked before restarting. For the infusion of medications, liquid forms should be used if possible. If pills are used they should be crushed to a fine powder and mixed with water. If the result is sticky or highly concentrated, dilute it further with water. When the tube is clogged. it can be irrigated with warm water or, if unsuccessful, a pancreatic enzyme solution injected. Reinsertion of a device, for example a stylet or guidewire, into a nasoenteric tube should never be tried because it can result in gastrointestinal tract injury. If there are unusual gastrointestinal symptoms like nausea, cramping, abdominal distention, or severe diarrhea, the infusion should be stopped and the clinician notified immediately. The clinician must assess the patient and the tube at this point.

When the nasogastric tube is used for gastric decompression or postoperative drainage, clinicians should understand the mechanics of nasogastric suction. Suction strength is inversely proportional to flow; therefore, the lower the flow rate through the suction lumen, the higher the suction strength. In addition, a suction force of more than 25 mm Hg causes tissue capillary fragility and may damage the gastric mucosa. One advantage of the double-lumen Salem sump tube over the Levin tube is that it allows constant airflow through the secondary lumen, keeping the necessary suction in the main lumen at a minimum. Therefore, the vent lumen must not be clamped or plugged. When the Levin tube is used, an intermittent suction pump should be connected to prevent injury of the gastrointestinal mucosa. The length of time the tube can be used depends on the patient's condition, feeding needs, and the tube design. With proper care and maintenance, most nasogastric tubes can be used for up to 30 days. For longer use, a percutaneous endoscopic gastrostomy tube should be considered (see Chapter 200, Percutaneous Endoscopic Gastrostomy Placement and Replacement).

## **CPT/BILLING CODES**

- 43219 Endoscopic guided insertion of plastic tube or stent
- 43752 Nasogastric or orogastric tube placement, necessitating physician's skill and fluoroscopic guidance
- 44500 Introduction of long gastrointestinal tube (e.g., Miller-Abbott)
- 74340 Introduction of long gastrointestinal tube (e.g., Miller-Abbott) with fluoroscopic guidance
- 89100 Duodenal intubation and aspiration; single specimen plus appropriate test procedure
- 89130 Gastric intubation and aspiration, diagnostic, each specimen, for chemical analysis or cytopathology
- 91105 Gastric intubation, and aspiration or lavage, for treatment (e.g., for ingested poisons)

#### **ICD-9-CM DIAGNOSTIC CODES**

- 014.82 Tuberculosis, gastrocolic, labs pending
- 261 Calorie deficiency, severe
- 263.9 Malnutrition, protein-calorie
- 536.2 Vomiting, persistent, nonpregnant
- 537.0 Gastric outlet obstruction, acquired or adult
- 560.1 Ileus, paralytic
- 561.81 Small intestine obstruction, due to adhesions
- 577.0 Pancreatitis, NOS or acute
- 577.1 Pancreatitis, chronic
- 578.0 Hematemesis or gastrointestinal hemorrhage
- 578.1 Hematochezia
- 578.9 Gastrointestinal bleeding, unspecified
- 787.01 Vomiting, NOS with nausea
- 787.03 Vomiting, NOS
- 977.9 Poisoning, unspecified drug or medicinal substances

# DIAGNOSTIC PERITONEAL LAVAGE

Eric Skye

Diagnostic peritoneal lavage (DPL) is a procedure that consists of two components. The first part involves the attempt to aspirate any free blood that may be present in the peritoneal cavity. If this initial portion of the procedure reveals hemoperitoneum, the test is considered positive and the remainder of the procedure is aborted. Hemoperitoneum in this circumstance is highly predictive of intraperitoneal injury and warrants a laparotomy.

If no free blood is obtained during the initial aspiration, the second portion of the procedure is conducted. This involves the introduction of normal saline or lactated Ringer's into the peritoneal cavity. The instilled fluid is subsequently drained from the peritoneal cavity and analyzed; results may ultimately indicate the nature of the intra-abdominal pathology.

Physical examination can be misleading in up to 45% of patients with blunt abdominal trauma. Spiral (helical/real-time) abdominal computed tomography and focused abdominal sonography for trauma (FAST; often performed at the bedside; see Chapter 225, Emergency Department, Hospitalist, and Office Ultrasonography [Clinical Ultrasonography]) are generally considered the preferred initial diagnostic choices for evaluation of patients with blunt abdominal trauma that may necessitate surgical intervention. However, DPL continues to be an important diagnostic tool in patients with blunt abdominal trauma who are hemodynamically unstable and for whom bedside ultrasonography is not available or they cannot be transported safely from the emergency department for imaging studies. DPL also serves as an adjunct in the evaluation of the patient with penetrating trauma.

#### **ANATOMY**

Diagnostic peritoneal lavage is traditionally performed in the midline, 1 to 2 cm below the umbilicus, which allows entry into the peritoneal cavity through the linea alba (the fibrous structure separating the rectus abdominis muscles). This fibrous band is relatively avascular and provides safe access for both the open and closed techniques. If DPL is performed above the umbilicus, the omentum frequently interferes with the catheter. When performed below the umbilicus, it is also usually easier to advance the catheter into a dependent location such as the pelvis.

#### **INDICATIONS**

- After blunt abdominal trauma in a patient who is either hemodynamically unstable or has an altered mental status or abnormal sensation (e.g., spinal cord injury) to assess for intraperitoneal hemorrhage or organ injury.
- After penetrating injuries (e.g., stab wound or gunshot wound) to the abdomen, flank, back, or lower chest to assess for intraperitoneal hemorrhage or organ injury. (Gunshot wounds that penetrate the peritoneum result in intraperitoneal injury in 98% of cases, so they warrant going straight to laparotomy; therefore, DPL should only be used for tangential gunshot wounds to the abdomen. Likewise, penetration into the peritoneum from a

thoracoabdominal wound results in a diaphragmatic injury that, by definition, needs to be repaired, so such injuries warrant going straight to surgery. Penetration through the retroperitoneum from the back or flank will cause a significant injury in 73% of cases; DPL may help determine whether the retroperitoneum has been traversed. Only two thirds of stab wounds to the anterior abdomen will penetrate the peritoneum, and of these, only 50% will require repair. Use of DPL in these cases may reduce the laparotomy rate.)

- After penetrating injuries to the abdomen, flank, back, or lower chest or blunt abdominal trauma in a patient who has an unreliable physical examination or in whom serial physical examinations are not practical (e.g., patient under anesthesia for orthopedic or neurosurgical procedure or taking postoperative analgesics).
- For the patient in shock after trauma that has other potential sources of hemorrhage (e.g., thoracic, retroperitoneal) to determine whether intraperitoneal hemorrhage is contributing to shock

## **CONTRAINDICATIONS**

## **Absolute**

Acute abdomen requiring immediate surgery is the only absolute contraindication.

#### **Relative**

If DPL is performed, the open technique should be used.

- Previous abdominal surgery (bowel may be adherent to midline; although DPL may be performed in area away from scar, compartmentalization of abdomen may have occurred, preventing blood circulation and causing false-negative DPL result).
- Coagulopathy.
- Pregnancy (DPL should be performed above the level of the uterine fundus; possibly below umbilicus in early-stage pregnancy).
- Morbid obesity (the locator needle may not be long enough to pierce abdominal wall).
- Pelvic fracture (use open technique above the umbilicus; closed technique may result in penetration of a retroperitoneal hematoma, a false-positive result, and decompression of the hematoma)
- Inability to insert Foley catheter to decompress bladder (e.g., urethral injury or stricture).

## **EQUIPMENT**

Commercially prepared kit or the following equipment:

- Skin-cleansing solution (povidone-iodine or chlorhexidine)
- Sterile gloves and mask

- Sterile marking pen (if area has not been marked indelibly before skin preparation)
- Sterile drapes
- 4 × 4 gauze squares
- 1% or 2% lidocaine with epinephrine
- Scalpel, no. 11 (and no. 15 blade for open technique)
- 9- to 18-Fr peritoneal catheter (kit equipped with catheterover-wire system for closed or Seldinger technique)
- 10-mL syringe for anesthetic
- 10-mL syringe for diagnostic tap
- 50-mL syringe, if using stopcock technique
- 18-gauge, 1½ to 3-inch locator needle; alternatively, an 18- or 20-gauge, 1½ to 3-inch spinal needle may be substituted
- 25- or 27-gauge,  $1\frac{1}{2}$ -inch needle
- Purple-topped blood collection tube
- Instruments for retractions such as hemostats or Army-Navy retractors
- Needle holder
- Nylon skin suture (4-0 or 5-0) on cutting needle
- Absorbable sutures (2-0 Vicryl) for peritoneum and fascia, if peritoneum is to be opened
- Sterile intravenous (IV) fluid (1 L warmed lactated Ringer's or normal saline, as opposed to fluid at room temperature, is preferred) and tubing
- Razor if open technique used
- Foley catheter
- Nasogastric tube
- Three-way stopcock (for use with 50-mL syringe) (optional)

#### **PRECAUTIONS**

- An open technique should be considered if the patient has a relative contraindication such as coagulopathy, pregnancy, previous abdominal surgery, pelvic fracture, or morbid obesity.
- A surgical assistant is recommended for an open DPL.
- DPL will not diagnose retroperitoneal hemorrhage.

## PREPROCEDURE PATIENT PREPARATION

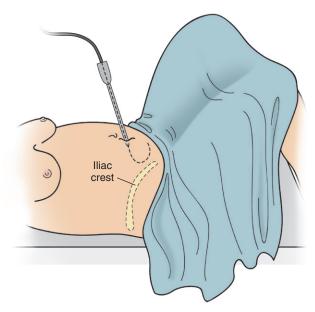

- Explain the procedure and its risks and benefits to the patient if possible (see the Complications section).
- Obtain verbal or written informed consent if possible.
- Place patient in the supine position.
- Use a Foley catheter and nasogastric tube for decompression of the bladder and stomach, respectively, if necessary.
- If necessary, use wrist restraints, especially for patients with altered mental status, to prevent contamination of the sterile field or self-injury.
- Consider procedural sedation (see Chapter 2, Procedural Sedation and Analgesia), especially if performing an open DPL.

**EDITOR'S NOTE:** Reviewing Chapter 201, Abdominal Paracentesis, may also be helpful.

#### **TECHNIQUE**

Procedural setup and fluid removal are identical for the open and closed techniques.

- Decompress the stomach and bladder. (See Chapter 203, Nasogastric and Nasoenteric Tube Insertion, and Chapter 110, Bladder Catheterization [and Urethral Dilation].)
- 2. Prepare the abdominal skin at the puncture site with standard preparation solutions such as chlorhexidine or povidone—iodine, and apply sterile drapes as appropriate. The ideal site is immediately inferior to the umbilicus (Fig. 204-1). Again, the supraumbilical approach may be used in second- or third-trimester pregnant patients, patients with prior lower abdominal surgery, or patients with pelvic fractures.

**Figure 204-I** Insertion of the needle into the peritoneal cavity in the midline, immediately inferior to the umbilicus.

3. Infiltrate the skin, subcutaneous tissues, and fascia with lidocaine with epinephrine.

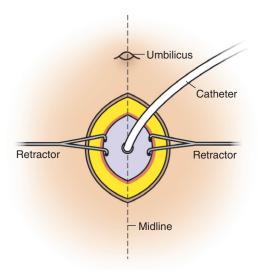

## A. Closed (Seldinger) Technique

This is the preferred technique, if not contraindicated.

- 4a. Attach an 18-gauge locator needle to the syringe and insert it into the midline, 1 to 2 cm inferior to the umbilicus, directed at a 45-degree angle to the skin and toward the pelvis. Applying negative pressure on the syringe, insert the needle through the skin and directly into the peritoneal space. Three "pops" are felt as the needle penetrates the skin, the fascia, and the peritoneum. If blood is aspirated during this step, it is considered a positive result. If not, proceed to step 5.
- 5a. The guidewire is then introduced through the 18-gauge needle, until only 7 to 10 cm of the guidewire remains outside the needle. You may then safely remove the needle, although there must be continuous control of the wire to prevent migration and injury to peritoneal structures. If there is difficulty inserting the guidewire or the patient complains of pain, both the needle and guidewire should be removed as a unit. To avoid shearing it off, do not withdraw the guidewire through the needle.
- 6a. Slide the peritoneal catheter over the wire using gentle twisting motions. With the closed technique, it may be necessary to make a small skin nick at the entry site with the scalpel to allow for passage of the lavage catheter.
- 7a. Remove the wire after the catheter is in the peritoneum. Proceed to step 8.

## **B.** Open Technique

- 4b. The skin should be shaved before preparation. Using the no.11 blade, create a 4- to 6-cm vertical skin incision in the midline.
- 5b. By blunt dissection, proceed down to the rectus fascia. Clamp and ligate any bleeders with absorbable suture before opening the fascia to prevent a false-positive test result. Open the rectus fascia using the no. 15 blade, and then proceed down to the peritoneum by sharp and blunt dissection.
- 6b. A 2- to 3-mm opening of the fascia is adequate for a semiopen technique. This technique provides room for the catheter to be inserted directly into the peritoneal space, even though visualization of the structures is not possible.

**Figure 204-2** Open technique, view from above. Superficial layers have been opened and are retracted away from the field of view. Catheter is inserted through the opened peritoneum directly into the peritoneal space.

7b. A slightly longer incision of the fascia is required for the open technique. The longer incision allows for the peritoneal space to be opened and visualized. The catheter can then be inserted into the peritoneal space under direct visualization (Fig. 204-2). Proceed to step 8.

## **Both Techniques**

- 8. Attach the syringe to the catheter and attempt to withdraw fluid. If more than 10 mL of blood is obtained, the patient should be prepared for emergent laparotomy. If the tap is dry, proceed to peritoneal lavage.
- Connect the IV tubing and infuse lactated Ringer's solution or normal saline. The amount infused is 1 L for adults and 15 mL/ kg for children.
- 10. The infused fluid is then removed by placing the IV bag on the floor and allowing the fluid to return by gravity. Alternatively, the IV tubing may be connected to a 1-L vacuum jar. The fluid should return at a steady rate of flow. If this flow is interrupted, it is probably due to omentum blocking the holes in the catheter. Placing pressure on the patient's abdomen may increase the flow; alternatively, the catheter may need to be withdrawn slightly and reinserted. If these maneuvers do not increase the return flow, a second liter of IV fluid may be infused.
- 11. At least 200 to 300 mL of lavage fluid should be returned for a valid test. After the maneuvers described previously have been performed, if less than 200 to 250 mL of return flow is obtained, a second catheter should be inserted. This should be inserted 1 cm below the first in the same manner as the first, in the midline. A second IV bag should then be attached and lowered to collect fluid via gravity drainage. After the fluid is removed, gently remove the catheter and apply pressure to the wound. When the open technique is used, close the peritoneum and rectus fascia with absorbable suture. The skin is then closed with nylon suture. If the closed technique was used, placement of a pressure dressing alone may suffice, although a single nylon skin suture may be necessary in some patients. A small amount of fluid should be transferred to the purple-topped tube for laboratory analysis.

## SAMPLE OPERATIVE REPORT

See the Sample Operative Report online at www.expertconsult.com.

## **COMPLICATIONS**

Complication rates range from 0.6% to 2.3% of all DPLs. There is no difference in complication rates among the techniques discussed.

- Bladder perforation
- Bowel perforation
- Lacerations of major vessels
- · Abdominal wall hematoma
- Abdominal wall dehiscence
- Infection (local, intraperitoneal, or systemic)
- False-positive result (vessel laceration during procedure) or falsenegative result (poor catheter placement or loss of fluid into the thoracic cavity)

## POSTPROCEDURE PATIENT EDUCATION

If the DPL result is positive, the patient should be informed of the need for emergent surgery. The patient with a negative DPL should be observed in the hospital for up to 24 hours. He or she should remain NPO during the initial observation period and receive analgesics as needed. Before discharge, it is useful to determine whether the patient can tolerate a regular diet. Also before discharge, educate the patient about the signs and symptoms of a complication such as bleeding, pain, vomiting, or infection. The patient should be given instructions regarding wound care.

#### INTERPRETATION OF RESULTS

The aspiration of greater than 10 mL of gross blood on entering the peritoneal cavity or through the locator needle is considered a positive finding. If not grossly bloody, fluid aspirated through the catheter should be sent for a red blood cell (RBC) count, a white blood cell (WBC) count, and possibly to check for amylase. Findings of more than 100,000 RBCs/mm<sup>3</sup> are also considered positive (half these numbers if 2 L of fluid were infused). Findings of 20,000/mm<sup>3</sup> to 100,000/mm<sup>3</sup> RBCs should be considered equivocal. In these patients an observation period of 12 to 24 hours should be considered. Two situations provide exceptions to these general rules: (1) stab wounds to the low chest where diaphragmatic injury is suspected (the diaphragm does not bleed as readily as other abdominal organs); and (2) gunshot wounds. The threshold for a positive RBC count should be 5000 RBC/mm<sup>3</sup> in these situations. Always be mindful of the hemodynamic stability of the patient when interpreting these results.

A WBC count greater 500 cells/mm³ is also considered a positive test and warrants laparotomy. Amylase may be elevated when there is injury to the gastrointestinal tract; however, a positive amylase test is neither sensitive nor specific. Confusion sometimes exists when a small amount of gross blood (<10 mL) is aspirated directly from the catheter (as opposed to the locator needle). This may have been the only blood located in a dependent portion of the abdomen and may not indicate the patient is unstable. The patient does not need a laparotomy if the subsequent lavage is negative.

# BONE MARROW ASPIRATION AND BIOPSY

Beth A. Choby

Bone marrow examination is a useful adjunct in the evaluation of various diseases, both hematologic and nonhematologic in origin. Bone marrow aspiration and biopsy supply additional clinical information when peripheral blood smears or other routine laboratory tests are inconclusive. Certain patients require bone marrow sampling for cytogenetic analysis, molecular studies, flow cytometry, or microbiologic cultures. The two procedures are performed sequentially and supply complementary information. Bone marrow aspiration allows visualization of cell morphology and a count of marrow cellular elements, whereas bone marrow (trephine) biopsy evaluates marrow cellularity and detects focal lesions such as metastatic cancer, lymphoma, or granulomas.

Bone marrow aspiration and biopsy are performed through one skin incision but sample separate areas of bone about 5 mm apart. The aspirate is usually collected first. A drawback of this approach is aspiration artifact, the artifactual hypocellularity and contamination with sinusoidal blood seen on the subsequent marrow biopsy specimen. Although the bone marrow biopsy can be done first, thromboplastic substances are released, making it less likely to obtain an adequate aspirate.

#### **ANATOMY**

Site selection for bone marrow aspiration depends on patient age and the clinician's experience. The posterior iliac crest is the most common site for bone marrow aspiration; bone marrow biopsy is nearly exclusively performed at this site (Fig. 205-1A). The sternum can be used for aspiration in adults, but it is never appropriate for biopsy (Fig. 205-1B; cardiac tamponade is a possibility if the posterior sternum were to be inadvertently penetrated). Figure 205-2 shows the Illinois needle, designed specifically for sternal bone marrow aspiration. The anterior iliac crest is an option for both bone marrow aspiration and biopsy, although the hard, thick cortical layer of bone makes this approach technically challenging. The anterior iliac crest is most often used when biopsy of the posterior iliac crest is contraindicated (e.g., significant obesity, physical disability, or presence of a cast). The anterior tibia is an option for marrow aspiration in infants younger than 18 months of age.

Aspiration and biopsy techniques for the posterior iliac crest are described in this chapter. Aspiration and biopsy at this site are both easily accessible and safe when performed properly.

#### **INDICATIONS**

- Evaluation of anemia or iron metabolism
- Thrombocytopenia
- Leukopenia or leukocytosis
- Pancytopenia
- Unexplained splenomegaly

- Work-up of fever of unknown origin
- Diagnosis and staging of leukemia and lymphoma
- Work-up for bone marrow transplantation
- Staging of nonhematologic cancers such as neuroblastoma
- Monitoring of chemotherapy- and radiation-induced damage from cancer treatment
- To obtain samples for chromosomal studies
- Work-up of dysproteinemia or lysosomal storage diseases
- Diagnosis of opportunistic infection in patients with human immunodeficiency virus infection/acquired immunodeficiency syndrome
- Unusual infections (e.g., tuberculosis, fungal infections)

#### CONTRAINDICATIONS

#### **Absolute**

- Hemophilia and related bleeding disorders
- Uncooperative patient
- Skin infection or osteomyelitis at the proposed biopsy site

## **Relative**

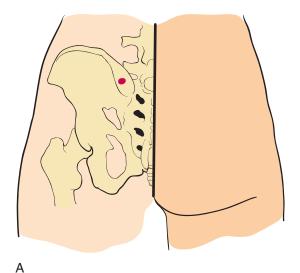

- Significant obesity
- Severe osteoporosis (risk of bone perforation and injury to underlying tissues)
- Previous radiation therapy at the biopsy site

**NOTE:** Isolated thrombocytopenia is *not* a contraindication to bone marrow aspiration or biopsy. When a patient requires anticoagulation therapy, it *does not* need to be reversed or held before the procedure. Patients taking anticoagulants should have an activated partial thromboplastin time (aPTT) and prothrombin time (PT)/international normalized ratio (INR) within the therapeutic range for heparin or warfarin before the procedure (i.e., not be excessively anticoagulated).

## **EQUIPMENT**

Necessary equipment is available in sterile, disposable, prepackaged kits (Fig. 205-3).

- Antiseptic solution (e.g., povidone–iodine or chlorhexidine)
- Sterile fenestrated drape
- 1% lidocaine
- 5- and 10-mL syringes
- 22-gauge (1½-inch) and 25-gauge (½-inch) needles
- No. 11 scalpel
- Bone marrow aspiration needle (Fig. 205-4)
- 11-gauge Jamshidi bone marrow biopsy needle (Fig. 205-5)

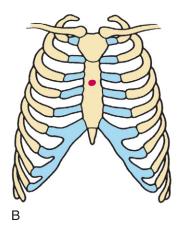

Figure 205-1 A, Posterior iliac sampling site. B, Sternal sampling site.

**Figure 205-2** Illinois needle for sternal bone marrow aspiration. (Courtesy of Cardinal Health, Dublin, Ohio.)

Figure 205-3 Prepackaged sterile Jamshidi bone marrow biopsy kit. (Courtesy of Cardinal Health, Dublin, Ohio.)

**Figure 205-4** Bone marrow aspiration needle. (Courtesy of Cardinal Health, Dublin, Ohio.)

- 10-mL syringe rinsed with ethylenediamine tetra-acetic acid (EDTA)
- EDTA (purple-topped) tube
- Glass slides (10)
- Bottle or tube with fixative (formalin)
- 4 × 4 gauze
- Pressure dressing and tape

#### **PRECAUTIONS**

Review the patient history and indications for bone marrow sampling. Question the patient about recent use of medications that might depress bone marrow function or stimulate blood formation (e.g., cytokines). Results of a complete blood count and peripheral blood smear should be reviewed before considering bone marrow aspiration and biopsy.

## PREPROCEDURE PATIENT EDUCATION

A cooperative patient is essential. Discuss indications for the procedure, as well as risks and benefits. Obtain a signed informed consent (see the sample patient consent form online at www.expertconsult.com). Inquire about any coagulation abnormalities or allergies (i.e., povidone–iodine or lidocaine). Explain that numbing the skin and periosteum, penetrating the iliac crest, and aspirating marrow is sometimes uncomfortable. Have the patient empty his or her bladder before the procedure. In overly apprehensive patients, premedication with a mild anxiolytic or analgesic is appropriate. Oral lorazepam (1 to 2 mg) and hydromorphone (1 to 2 mg) given 60 to 90 minutes before the biopsy lessen pain and induce varying degrees of amnesia.

## **TECHNIQUE**

Optimal bone marrow evaluation requires examination of both the marrow aspirate and a biopsy specimen (smear preparations and sections). Obtaining both samples simultaneously is better in terms of cost, patient comfort, and diagnostic information gleaned. The aspirate is usually performed first. The following instructions describe bone marrow aspiration and biopsy using the posterior iliac approach.

**Figure 205-5 Jamshidi bone marrow biopsy needle.** (Courtesy of Cardinal Health, Dublin, Ohio.)

## **Bone Marrow Aspiration**

- 1. Have the patient lie either in the lateral decubitus position with knees flexed at the hip or in the prone position. Identify each iliac crest and follow it to its posterior superior spine (see Fig. 205-1). Mark this location using ink or pressure from a needle
- 2. Put on sterile gloves and prepare the biopsy area with 10% povidone-iodine antiseptic in a circular pattern. Drape the site with the fenestrated sterile drape. Position the fenestration over the center of the intended biopsy site.
- 3. Using the 25-gauge needle and 5-mL syringe, make a skin wheal with 1% lidocaine. Switch to the 22-gauge needle/5-mL syringe to anesthetize deeper structures. Introduce the needle until the periosteum is encountered. Infiltrating the periosteum with 1 mL of lidocaine is important because most of the bone pain fibers are located here. Inject 2 to 3 mL of lidocaine along the outgoing tract as the needle is removed.
- Make a 2- to 3-mm skin incision with the scalpel to enhance insertion of the aspiration needle.
- 5. Insert the aspiration needle perpendicularly to the bone; make sure the stylet is locked in place. Insert the needle until it rests against the anesthetized periosteum. Rotate the needle clockwise and counterclockwise using enough force to penetrate the bony cortex. "Give" is felt when the marrow cavity is entered. Stop pushing and check that the needle remains stationary without support.
- Remove the stylet and attach a 10-mL EDTA-rinsed syringe. Warn the patient that he or she will experience pain as the marrow is aspirated. Pull the plunger and rapidly aspirate 0.2 to 2 mL of marrow for slide preparation (higher volumes dilute the specimen with blood). If more material is needed for other studies, an additional 5 mL of aspirate may be withdrawn.
- 7. Give the aspirated material to an assistant for slide preparation. Aspirate quality is assessed by the presence of grossly visible marrow spicules. Thin films should be prepared quickly with minimal specimen manipulation. Several drops of aspirate are placed on the edge of a glass slide while the edge of another slide is used to thinly spread the aspirate across the first slide. Four slides are prepared and allowed to air dry. Slides are stained with either Wright or May-Grünwald-Giemsa stain.

- 8. Place the remaining aspirate in a tube with EDTA, mix well, and allow it to clot for later fixation and processing by the histologist. If extra material is needed for flow cytometry, culture, cytogenetics, or other special studies, use another sterile syringe to withdraw more aspirate from the aspirate needle.
- 9. If a "dry tap" is encountered (no aspirate despite seemingly good needle placement), replace the stylet and advance the needle 1 to 2 mm. If still no aspirate is obtained, remove the needle and reinsert it at another part of anesthetized periosteum near the
- 10. Once the aspirate sample is judged adequate, replace the stylet and remove the entire needle using a twisting motion.
- 11. Place dry gauze over the site and apply pressure until the bleeding stops. Cover the area with an adhesive bandage unless proceeding with a bone marrow biopsy.

## **Bone Marrow Biopsy**

Bone marrow biopsy is performed immediately after aspiration. Once the bone marrow aspiration needle is removed, the following steps are taken:

- 1. Confirm that the stylet of the Jamshidi biopsy needle is locked into place with the cap secured (see Fig. 205-5). Place the capped end in the palm of your hand so that the shaft lies between the index and middle fingers. Introduce the needle into the skin incision and push past the soft tissue until the periosteum of the posterior iliac spine is reached. Position the needle at least 5 mm away from the periosteal entry point used for the aspirate collection (to avoid aspiration artifact). Using clockwise and counterclockwise rotation with considerable downward pressure, pierce the bony cortex and enter the marrow. The cortex is usually about 1 cm thick and entrance into the marrow cavity is detected by decreased resistance (Fig. 205-6).
- 2. Unlock the cap and remove the stylet.
- 3. Slowly and gently advance the needle millimeter by millimeter (1.5 to 2 cm) with an alternating clockwise-counterclockwise motion to obtain an adequate specimen.
- 4. Pull the needle back 2 to 3 mm and redirect the tip approximately 15 degrees. Advance the needle 2 to 3 mm forward in this new position to break off the specimen.

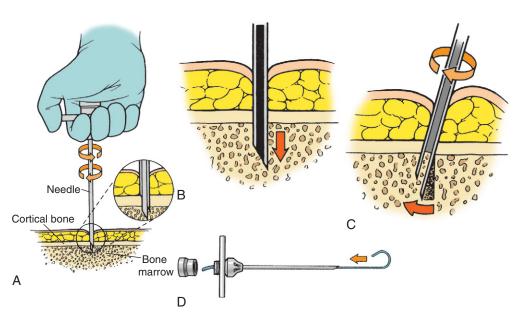

Figure 205-6 Technique for obtaining a bone marrow biopsy specimen. A, The needle is advanced through the cortical bone. B, The stylet is removed and the needle advanced an additional 1.5 to 2 cm using downward rotational force. C, The needle tip is redirected 15 degrees and rotated to break off the specimen. D, The probe is used to push the specimen onto gauze, threaded through the needle tip toward the biopsy needle handle.

Figure 205-7 Biopsy specimen from bone marrow biopsy with Jamshidi needle. (Courtesy of Cardinal Health, Dublin, Ohio.)

- 5. Rotate the biopsy needle 360 degrees four times to the right and then four times to the left.
- 6. Remove the needle from the patient using rotational movements. The sample should stay in the Jamshidi needle.
- 7. Remove the biopsy specimen by inserting the blunt probe into the needle tip, pushing the specimen toward the hub/handle and out onto sterile gauze. Take care not to injure yourself on the sharp cutting edge (see Fig. 205-6D) of the needle tip.
- 8. Prepare the specimens or give the sample to the technician for preparation. Touch preparations (five) are made by gently pressing five glass slides against the biopsy specimen. The slides are usually stained with Wright or Giemsa stain. The remaining biopsy sample is placed into a container with formalin and sent for sectioning and staining (Fig. 205-7).
- 9. Cover the biopsy site with gauze and apply pressure until the bleeding stops. Cover the area with gauze and an adhesive bandage to form a pressure dressing. The patient should lie on the biopsy site for 60 minutes.

#### SAMPLE OPERATIVE REPORT

See the Sample Operative Report online at www.expertconsult.com.

## **COMMON ERRORS**

- Failure to adequately anesthetize the periosteum. Most of the bone pain fibers are located in this layer. The periosteum should be gently probed or tested with the sharp point of the 22-gauge needle before aspiration or biopsy. If the patient experiences sharp pain, an additional 1 to 2 mL of lidocaine should be injected.
- Inadequate specimen length obtained on the bone marrow biopsy. The ideal length of an adequate bone marrow biopsy is not well defined. Specimen lengths ranging from 1.6 to 3 cm have been recommended by various authorities. Because the core biopsy shrinks by up to 25% during processing, obtaining an adequate biopsy is important.
- Dry tap. A dry tap is the failure to aspirate fluid or find bone marrow particles during bone marrow aspiration. The most common cause is faulty positioning of the aspiration needle into the marrow cavity. The stylet can be replaced and the aspiration needle advanced to attempt a second aspirate. Dry taps occur in 4% to 7% of cases. A repeat dry tap is suggestive of myelofibrosis, hairy cell leukemia, aplastic anemia, myeloma, lymphoma, or leukemia. A bone marrow biopsy is then required to obtain touch imprints that "substitute" for the aspirate.
- Preparation of low-quality aspirate smears. Bone marrow clots quickly, so aspirate slides are usually prepared at the bedside by the provider or a trained technician. The simplest preparation is a wedge technique similar to that used for peripheral blood smears. A drop of marrow is placed at one end of a glass slide while a second slide held at a 30-degree angle is used to feather the aspirate across the first slide. Particle crush methods and coverslip preparations are more challenging to prepare.
- Dilution by peripheral blood. This happens when a large volume of bone marrow is aspirated.

## **COMPLICATIONS**

Complications of bone marrow aspiration and biopsy are exceedingly rare. Major adverse events occur 0.2% of the time. Adverse outcomes include the following:

- Retroperitoneal hemorrhage or bowel damage from perforation of the iliac bone in osteoporotic patients
- Hemorrhage at the biopsy site
- Infection at the biopsy site (unusual if sterile technique is followed)
- Perforation of the lower sternal plate resulting in cardiac tamponade and sudden death
- Breakage of the bone marrow needle or handle separation during insertion into the bone (rare)
- Unilateral lower extremity weakness or numbness due to irritation of the sacral nerve plexus (rare and transient)
- Pain (usually resolves within a day)

## POSTPROCEDURE MANAGEMENT

The patient lies on the bandaged biopsy site for 1 hour while being monitored. If the patient was thrombocytopenic before the procedure, a pressure bandage is applied and the site checked frequently for excessive bleeding.

#### POSTPROCEDURE PATIENT EDUCATION

Emergency contact numbers are provided and the patient instructed to call in case of bleeding, pain, fever, or erythema at the biopsy site. The pressure dressing is removed after 12 to 24 hours. Pain medication should be provided as needed.

#### INTERPRETATION OF RESULTS

The bone marrow aspirate and biopsy specimens are examined by a trained histopathologist who interprets the results. A written report is generated and sent to the provider who performed the tests. Providing adequate clinical information aids the pathologist in reaching an accurate diagnosis.

## LUMBAR PUNCTURE

Jeffrey A. German • John O'Brien

Lumbar puncture is performed to obtain cerebrospinal fluid (CSF) and is vital for making many neurologic diagnoses. In ordinary circumstances, the adult brain floats in about 150 mL of CSF and is capable of manufacturing about 500 mL/day. Examination of the CSF remains the most direct and accurate method of determining if there is a central nervous system infection. Lumbar puncture should be a routine procedure in febrile adults with an altered mental status and no source of fever and in febrile children who appear toxic, regardless of age. Whereas computed tomography (CT) and magnetic resonance imaging have somewhat superseded lumbar puncture for making various neurologic diagnoses, they have also increased the safety of performing a lumbar puncture. Although the sensitivity of CT for making the diagnosis of subarachnoid hemorrhage (SAH) can range from 92% to 98% when performed within 24 hours of the onset of symptoms, it decreases to 75% when performed 48 to 72 hours after the onset of symptoms. It is often negative in patients with a sentinel bleed, which occur in 20% to 50% of patients, hours, days, weeks, or months before a major SAH. Xanthochromia, when measured by spectrophotometry, has a sensitivity approaching 100% when performed between 12 hours and 2 weeks after SAH; therefore, a lumbar puncture must be performed if SAH is still suspected with a negative CT. If adequate time has elapsed (>2 hours), xanthochromia and red blood cells (RBCs) should be noted. If there has not been adequate time for RBCs to migrate to the lumbar spine area, a cerebral angiogram or repeat lumbar puncture in 12 to 18 hours should be performed. Although lumbar puncture is generally a diagnostic procedure, it can also have therapeutic applications (e.g., pseudotumor cerebri, elevated CSF pressure).

## **INDICATIONS**

- Suspected central nervous system infection (e.g., meningitis, encephalitis)
- Suspected SAH (If available, a CT scan should be done first. It
  will exclude certain causes for increased intracranial pressure.
  However, CT has a false-negative rate of up to 25% for blood.
  With a bleed, xanthochromic color of CSF [visible >2 hours after
  the bleed] and an abnormal RBC count [>1000/mm³] should be
  noted.)
- Pseudotumor cerebri (therapeutic) or normal-pressure hydrocephalus (diagnostic)
- Guillain-Barré syndrome (very high CSF protein level [>200 mg/ dL])
- Multiple sclerosis (Usually the immunoglobulin G [IgG] level is elevated and oligoclonal banding is present on electrophoresis.)
- Spinal analgesia
- Lupus cerebritis (CSF may be normal, but some reports have noted elevated levels of anti-DNA antibodies, IgG, oligoclonal banding, immune complexes, interleukin-6, and the chemokine CXCL10.)
- Acute demyelinating disorders (e.g., encephalomyelitis, transverse myelitis)

- Dementia (if normal-pressure hydrocephalus, syphilis or other chronic infection, or vasculitis is suspected as a cause)
- Meningeal carcinomatosis
- Unexplained neurologic disorders if CT is negative (e.g., altered level of consciousness, polyneuropathy)
- Intrathecal antibiotics or chemotherapeutics
- Imaging procedures (e.g., myelography, cisternography)

#### **CONTRAINDICATIONS**

- Local skin infection (absolute contraindication)
- Raised intracranial pressure (suggested by the presence of papilledema, suspected SAH, or clinical risk factor[s] for intracranial pathology [Box 206-1] unless the CT scan is negative)

**NOTE:** The absence of papilledema is not always a reliable sign of normal intracranial pressure because it often takes more than 48 hours for papilledema to develop. Papilledema will be absent in up to 15% of adults and 50% of children with early increased intracranial pressure.

Supratentorial mass lesions (should be evaluated by CT scan first)

**NOTE:** Certain CT findings indicate a predisposition to herniation if a lumbar puncture is performed: (1) a midline shift, (2) a loss of the suprachiasmatic and basilar cisterns, or (3) any evidence of a posterior fossa mass or obliteration of the superior cerebellar cistern or the quadrigeminal plate cistern caudal to the midbrain.

# Box 206-1. Clinical Findings Associated with Increased Risk of Intracranial Pathology

Abnormal language
Age 60 years or older
Altered level of consciousness
Arm drift
Facial palsy
Gaze palsy
History of central nervous system disease
Immunocompromised state
Inability to correctly answer two questions
Inability to follow two consecutive commands

Seizure within 1 week of presentation
Visual field abnormality

From Straus SE, Thorpe KE, Holroyd-Leduc J: How do I perform a lumbar puncture and analyze the results to diagnose bacterial meningitis? JAMA 296:2012–2022, 2006.

- Severe bleeding diathesis or coagulopathy (e.g., platelet count dropping rapidly or <20,000/mm³ [platelets should be transfused]), or anticoagulated patient (international normalized ratio >1.4) (relative contraindications; however, the most experienced clinician should perform the procedure using the smallest-gauge needle available)
- Unstable patient (If patient has hypotension, shock, status asthmaticus, or unstable airway, lumbar puncture should be delayed until patient is stable.)

**NOTE:** Meningitis itself can cause increased intracranial pressure. Consequently, patients with decorticate or decerebrate posturing, focal neurologic signs, or no response to pain should receive antibiotics without lumbar puncture even if the CT scan is negative.

 Uncooperative adult patient (Lumbar puncture should be delayed until patient is stable.)

## PREPROCEDURE PATIENT PREPARATION

Indications, alternatives, risks, potential benefits, and expected results should be discussed with the patient or representative, and he or she should sign an informed consent form (see the sample patient education and consent forms online at www. expertconsult.com). The patient should expect some discomfort with injection of the local anesthetic and as the spinal needle is inserted. It will be important for him or her to remain very still during certain portions of the procedure. If the patient is a child or minor, the parents or caregiver can be asked if they would like to be present during the procedure.

#### **EQUIPMENT**

Spinal tray (Fig. 206-1) containing the following:

- Povidone-iodine skin swabs
- Alcohol swab
- Fenestrated drape and sterile gloves
- Manometer, three-way stopcock
- 1% lidocaine
- 3-mL syringe with 20- to 23-gauge needle (for drawing up anesthetic)
- 25- to 27-gauge skin needle
- 20- to 22-gauge spinal needle plus a spare (traditional is Quincke spinal needle with sharp, beveled end)\*
- Four numbered, capped test tubes
- Sterile dressing (Band-Aid)
- Pulse oximetry (optional, may be especially helpful for children)
- Lidocaine—prilocaine (eutectic mixture of local anesthetic or EMLA) cream (optional; although shown to be more effective in adults than lidocaine infiltration alone, it must be applied 30 to 60 minutes before the procedure and local anesthetic should still be injected)
- 1- mL syringe (optional, but may be helpful if CSF not flowing)
- 21- to 25-gauge butterfly needle (optional)

**NOTE:** Some experts advocate use of a butterfly needle in children; the tubing is then used to estimate opening pressure. However, epidermoid tumors due to implanted dermal cells are associated with use of a spinal needle without a stylet.

## **TECHNIQUE**

1. In patients with focal neurologic findings, altered mentation, immunocompromise, suspected SAH, or papilledema (see Box 206-1), consider CT scan first.

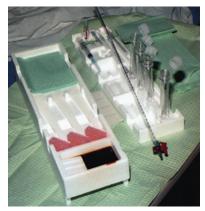

Figure 206-I Lumbar puncture equipment tray.

**NOTE:** If meningitis is suspected, the initiation of antibiotics should not be delayed while awaiting the CT scan results before performing the lumbar puncture.

2. Position the patient near the edge of the bed (or the examination table) in the lateral decubitus or sitting position. Slightly flex the neck anteriorly. If the patient is lying down, ask him or her to "roll up into a ball" with the knees drawn up to the abdomen (Fig. 206-2). The shoulders and pelvis should be aligned vertically without forward or backward tilt. If the patient is lying down, his or her shoulders, back, and hips should be exactly perpendicular to the bed. Identify the L3-L4 interspace (a line drawn between the superior aspect of the iliac crests intersects the body of L4). If necessary, the L2-L3 or L4-L5 interspaces can be used (Fig. 206-3). Some clinicians mark the site with a pen or make a small indention with the hub of a needle.

**NOTE:** Although the lying position may be more comfortable for the patient, the sitting position is most commonly used in adults. With the patient sitting, it is usually easier to identify the midline and palpate the spinous processes, particularly when the patient is obese.

- 3. Open the spinal tray in a sterile manner. Put on sterile gloves and preassemble the manometer. It is usually in two pieces that slide together. Insert the manometer into the vertical port of the three-way stopcock and set this assembly to the side on the sterile field. Next, open the numbered test tubes. Place them upright, in order, in the slots provided in the plastic tray.
- 4. Prepare the skin at the selected interspace, plus the one above and below, with an antiseptic solution such as povidone—iodine. The prepared area is usually at least 10 cm in diameter; cover the area with a fenestrated drape. If lidocaine—prilocaine (EMLA) cream is used, it must be applied at least 30 to 60 minutes before beginning the procedure, and it only anesthetizes the skin and subcutaneous tissue, so a local anesthetic will still need to be injected.

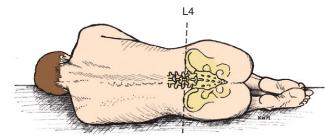

Figure 206-2 Location of anatomic landmarks.

<sup>\*</sup>Atraumatic spinal needles have been shown to reduce the complication of spinal headache (i.e., less risk of a CSF leak).

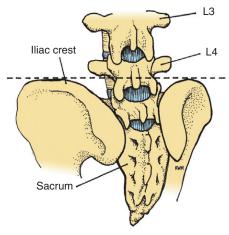

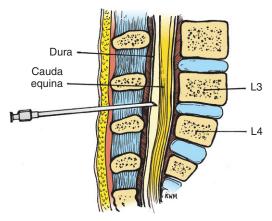

Figure 206-3 Line across the iliac crests intersects the body of L4.

- 5. Draw 3 mL of 1% lidocaine into the syringe with the 20- to 23-gauge needle. Administer local anesthetic with the skin needle and raise a wheal over the L3-L4 interspace in the midline. Inject a small amount deeper into the posterior spinous region, in the direction that the spinal needle will follow. (Some experts perform a field block for anesthesia. Sensation to the interspinous ligaments and the periosteum is supplied by the recurrent spinal nerves, which branch off the nerve roots exiting the spinal canal at the same level. A field block is performed by first injecting a small amount of local anesthetic into the interspinous ligaments in the midline, and then above and below the intended location of the lumbar puncture. The block is completed by redirecting the needle laterally, to both sides of the intended lumbar puncture site, and injecting a small amount of anesthetic.)
- 6. Palpate the posterior spinous process. Using this and the umbilicus as landmarks, insert a 20- or 22-gauge spinal needle through the skin in the midline. The needle can be held with both index fingers and advanced with the thumb(s), or it can be guided with a thumb and forefinger near the puncture site while the other hand advances the needle by putting pressure on the hub. Angle the needle about 15 degrees cephalad, toward the umbilicus, keeping it level with the sagittal midplane of the body (Figs. 206-4 and 206-5). Keep the bevel of the needle parallel to the longitudinal axis of the spine (point turned upward or downward with the patient in the lateral decubitus position, or to one side if the patient is sitting) as the needle is advanced. If bone is encountered, withdraw the needle slightly and change its angle, usually more cephalad. Depending on the

**Figure 206-4** Proper angle for entering spinal canal (with patient seated). Needle is directed cephalad.

**Figure 206-5** Drop in resistance will be felt as the needle penetrates the dura.

size of the patient, after the needle has advanced about 3 to 4 cm, stop, withdraw the stylus, and check the hub for fluid. If there is no fluid, replace the stylus and advance another fraction before repeating this again. Usually a slight "pop" is felt as the spinal needle penetrates the dura; however, this may not be felt using a Quincke needle. Advance the needle 1 to 2 mm farther and withdraw the stylus. Rotating the needle 90 to 180 degrees is sometimes helpful if no fluid returns. If the patient experiences pain radiating down one leg or the tap is "dry," remove the needle completely and make an attempt at a different interspace. A dry tap is more often due to a poorly positioned patient or an improperly placed needle than to an obliterated subarachnoid space; often the needle tip has migrated laterally out of the midline. For repeated dry taps, reposition the patient from lying to sitting, or vice versa, and attempt puncture again while making sure the needle is directed toward the midline. Approach from a lateral site can also be utilized as described later. CSF may fail to flow in certain low intracranial pressure situations (e.g., dehydrated patient), so gentle suction with a 1-mL syringe may be helpful.

**NOTE:** For very large or obese patients, it may be impossible to palpate the spinous process for use as a landmark. Ultrasonography may help locate the bone in the spinous process (see Chapter 225, Emergency Department, Hospitalist, and Office Ultrasonography [Clinical Ultrasonography]).

- 7. Once fluid is obtained, the needle hub should be "anchored," or held firmly between the thumb and index finger of one hand that is braced against the patient's back, whenever anything is attached or removed from the needle using the other hand. Next, place the end of the stopcock with the attached manometer onto the hub of the needle. Have the patient straighten the legs and relax his or her position so that the opening pressure is not artificially elevated. The CSF should rise in the manometer to the level of the opening pressure. The pressure is accurate only if the patient is lying on his or her side in a relaxed position. If tubing is in between the needle and manometer, the base of the manometer should still be held at the level of the needle hub for accurate readings. Note the color of the fluid and the opening pressure. CSF pressure should oscillate slightly with respiration (and sometimes with the pulse).
- 8. In case the fluid is bloody and does not clear after the first few drops of fluid (bloody tap), replace the stylus and remove the spinal needle. Select an alternative lumbar interspace above or below the current level and reattempt lumbar puncture as described in steps 4 through 7.

**NOTE:** Bloody CSF due to SAH will *not* clot. Also, after spinning in a centrifuge, the supernatant is xanthochromic.

TABLE 206-1 Normal Cerebrospinal Fluid Values			
Value	Term Infant	Child	Adult
Opening pressure (mm H <sub>2</sub> O)	50–80	50–80	70–180
WBC count (WBC/mm³)	8 (range, 0–22)	<7	<5
Neutrophils	61%	None	None
Glucose (ratio of blood/CSF glucose and CSF level [mg/dL])	44%–128% (34–119)	50% (40–80)	60%–70% (50–80)
Protein level (mg/dL)	20–170 (mean, 90)	5–40	15–45

CSF, cerebrospinal fluid; WBC, white blood cell.

- 9. Turn the stopcock to allow the CSF to flow into the test tubes. Keep track of the order in which they are filled. Fill at least three test tubes with 2 to 3 mL of CSF each (at least 2 mL is necessary for cytology or antigen testing). Label each tube in the order it was collected. A fourth tube can be filled and frozen in case further studies are needed. Table 206-1 shows normal CSF values, and Table 206-2 lists recommended CSF tests. Tube 1 is most likely to be contaminated with blood from the needle insertion; therefore, tube 3 should be tested for the cell count and differential. Minor blood contamination usually clears by the third tube.
- Once you have obtained enough CSF, replace the stylus and withdraw the needle.
- 11. Cover the puncture site with a sterile dressing.
- 12. For a therapeutic lumbar puncture (i.e., for pseudotumor cerebri), remove enough CSF to reduce the closing pressure to 100 mm H<sub>2</sub>O or less (usually 25 to 35 mL of CSF). For a diagnostic tap, removal of 35 to 50 mL may result in transient improvement in gait or cognition for suspected normal-pressure hydrocephalus.

## **Technique for Lateral Approach**

The lateral approach technique may be preferred in elderly patients with calcified supraspinous and intraspinous ligaments. It may also be used if the midline approach has failed. The patient may be in either the sitting or the lateral decubitus position, and should be prepared and draped in the same interspaces as described previously. Anesthesia should be applied/injected in a location 1.5 to 2 cm lateral to the midline, on either side if the patient is in the sitting position or on the lower side if the patient is in the lateral decubitus position. Local anesthetic should be injected in the location and direction that the spinal needle will follow. The spinal needle should be directed approximately 15 degrees cephalad and 20

degrees to the midline (Fig. 206-6). From this location, the needle usually bypasses the supraspinous and infraspinous ligaments, and instead penetrates the erector spinae muscles and the paraspinous ligaments, and then the ligamantum flavum, dura, and subarachnoid space. If bone is encountered, the needle should be withdrawn slightly and redirected in the same angle toward the midline but slightly more cephalad. The remainder of the procedure is as described previously.

## **Technique for Pediatric Patients**

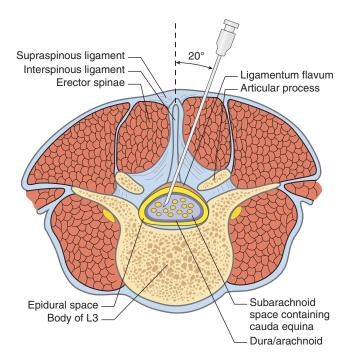

The preferred position for infants (especially premature infants and neonates) is with the infant seated with the head only slightly flexed. Overflexion of the head can lead to hypoxia and respiratory arrest in young infants. Likewise, increased intra-abdominal pressure caused by flexing the knees into the abdomen may lead to compression of the diaphragm and hypoxia. Consequently, the child should be monitored visually and possibly with pulse oximetry during the procedure. Preoxygenation with 100% oxygen by face mask for 2 to 5 minutes before the procedure may prevent hypoxia. If the procedure is performed with the child lying, a modified lateral decubitus position should be used (i.e., hips flexed only to 90 degrees). Draping should be done conservatively to avoid interfering with any infant monitors. The skin can be anesthetized initially with a patch containing EMLA cream, if it is available, followed 30 to 60 minutes later by an injection with lidocaine. The spinal needle is directed slightly cephalad. In young infants a "pop" or change in resistance may not be felt as the needle penetrates the dura. Use a 20- to 22-gauge, 1½-inch needle for infants. A 3½-inch spinal needle can be used in children older than 12 years of age.

**NOTE:** Local anesthetic should be used in all children. There is evidence that pain perception is present even in premature neonates.

#### **COMPLICATIONS**

• Post–lumbar (post–dural) puncture headache occurs in 10% to 25% of patients and is usually self-limited. The headache usually lasts for only a few days, but may last longer than a week and can be debilitating. Ninety percent of spinal headaches occur within 48 hours after dural puncture, but it may occur up to 14 days later. It is exacerbated by sitting upright and is relieved by lying down. The incidence increases with repeat lumbar punctures in a patient. The incidence is reduced by using a higher-gauge (24- to 27-gauge) or atraumatic needle, but these smaller needles have a higher failure rate and take longer to obtain samples, and opening pressures cannot be measured; therefore, in practice, a 22-gauge needle is usually used. The incidence of headache is also reduced by keeping the bevel of the needle oriented parallel to the long axis of the patient's spine, thereby spreading rather than cutting

TABLE 206-2 Recommended Cerebrospinal Fluid Tests				
Tube 1: Bacteriology	Tube 2: Biochemistry	Tube 3: Hematology	Tube 4: Optional	
Gram stain Acid-fast stain* Culture Bacteria Fungal* Tuberculosis* Viral*	Glucose Protein Protein electrophoresis* (need concurrent serum study)	Cell count Differential	VDRL* India ink* Cryptococcal antigen* Cytology* Oligoclonal bands* Myelin basic protein* Countercurrent immunoelectrophoresis* Serologic and genetic tests for other microorganisms* Anti-DNA antibodies, immune complexes, interleukin-6, chemokine, and CXCL10 levels*	

**Figure 206-6** Using the lateral approach, the needle is inserted 1.5 to 2 cm lateral to the midline and is directed approximately 20 degrees toward the midline and 15 degrees cephalad. (From Fong B, VanBendegom JM: Lumbar puncture. In Reichman EF, Simon RR [eds]: Emergency Medicine Procedures. New York, McGraw-Hill, 2004, pp 859–880.)

the fibers of the ligamenta flava. Replacement of the stylet before removing the spinal needle has also been shown to decrease the risk of spinal headaches. Oral caffeine, 300 mg, or theophylline, 200 mg, if not contraindicated, may provide relief in adults. Intravenous caffeine benzoate, 500 mg given over a few minutes, can also be used to treat refractory spinal headaches in adults. A repeat dose can be given in 1 hour for an 85% chance of alleviation of symptoms. Twenty-four hours after lumbar puncture, if there has been no relief from caffeine, an epidural blood patch can be performed. This is performed by injecting 15 mL of autologous blood into the dural space. Although the mechanism of action is unclear, it usually provides immediate relief in up to 85% of patients. After a second patch is performed, if necessary, 98% of patients experience relief. Because the patient already has a spinal headache, the most experienced clinician available should probably perform the blood patch(es). Transient complications of the blood patch include back pain, paresthesias, radiculopathies, and weakness; rarely, spinal subdural hematoma has been reported.

- Epidermoid tumors have been associated with lumbar punctures performed in the neonatal period, especially when needles are used without a stylus.
- Seizures have been reported in a small percentage of patients with post-dural puncture headaches.
- A traumatic or "bloody" tap from inadvertent puncture of the spinal venous plexuses is possible. This is self-limiting in the majority of patients, but could lead to a spinal hematoma in patients with bleeding disorders. Some authorities recommend sending the first and fourth tubes for cell count (RBCs and WBCs with a differential) if a traumatic tap is suspected. The RBC count will decrease from tube 1 to tube 4 in the case of a traumatic tap. A correction can be made for CSF leukocytes and CSF protein if the tap is traumatic. For every 700 RBCs, CSF leukocytes increase by 1 and CSF protein rises 1 mg/dL.

- Brain herniation from a supratentorial mass or increased intracranial pressure is another complication. Always check the fundi for papilledema before performing lumbar puncture. If a tumor, intracranial bleed, intracranial pathology (see Box 206-1), or marked increased pressure is suspected, an emergency CT scan should be obtained before a lumbar puncture is done, to reduce the chance of herniation.
- Intracranial subdural hematoma is a rare complication, and is due
  to the same mechanism that causes post—lumbar puncture headache (especially with persistent CSF leakage) or brain herniation,
  that is, downward displacement of the brain. Such displacement
  can result in tearing of the bridging veins and lead to bilateral or
  unilateral subdural hematoma.
- Spinal epidural or subdural hematoma can present with paraplegia, lower extremity weakness, sensory deficits, or incontinence. Anticoagulated patients or those with a coagulopathy should be monitored closely for this complication.
- Paresthesias in the lower extremities are common and usually transient, but in rare cases can last for more than a year.
- Local pain in the back may be due to injury of the local tissue, the periosteum, or the spinal ligaments. Mild, transient pain is common.
- Disk herniation is a very rare complication and is caused by a needle passing through the entire subarachnoid space and into the annulus fibrosus. It can also result in diskitis or vertebral collapse.
- Cranial nerve neuropathies involving cranial nerves III, IV, V, VI, VII, and VIII have been reported. These are usually transient, present with visual and auditory symptoms, and are caused by traction on the nerve due to low intracranial pressure after lumbar puncture.
- Nerve root aspiration is a possible complication. Replacing the stylus before withdrawing the needle may prevent aspiration of nerve roots. Very rarely, nerve root diverticula can rupture as a result of lumbar puncture, causing a brief CSF leak and a spinal headache.
- Meningitis resulting from the procedure is a theoretical complication. Bacteremia is not a contraindication to lumbar puncture.

#### **PATIENT EDUCATION GUIDES**

See the sample patient education and consent forms available online at www.expertconsult.com. A video of ultrasonically directed lumbar puncture can be purchased at www.Sonosite.com.

#### **CPT/BILLING CODES**

- 62270 Spinal puncture, lumbar, diagnostic
- 62272 Spinal puncture, therapeutic, for drainage of cerebrospinal fluid
- 62273 Injection, epidural, of blood or clot patch
- 62311 Injection, single, of diagnostic or therapeutic substances; (including anesthetic, antispasmotic, opioid, steroid, other solution), lumbar, sacral

#### **ICD-9-CM DIAGNOSTIC CODES**

- 239.7 Meningeal carcinoma or neoplasm
- 294.1 Dementia in conditions classified elsewhere
- 320.0 Meningitis due to Hemophilus meningitis
- 320.1 Pneumococcal meningitis
- 320.2 Streptococcal meningitis
- 320.3 Staphylococcal meningitis
- 320.9 Meningitis due to unspecified bacterium
- 322.0 Nonpyogenic meningitis
- 322.9 Meningitis, unspecified
- 323.9 Encephalitis, myelitis, and encephalomyelitis, unspecified cause

#### 1414 HOSPITALIST

- 340 Multiple sclerosis348.2 Pseudotumor cerebri
- 357.0 Guillain-Barré syndrome
- 430 Subarachnoid hemorrhage
- 710.0 Systemic lupus erythematosus
- 852.00 Subarachnoid hemorrhage after injury without open intracranial wound, unspecified state of consciousness

## MECHANICAL VENTILATION

Joe Esherick

Modern mechanical ventilation was developed out of necessity during the polio epidemic of the 1930s. The original machines were negative-pressure ventilators, known as "iron lungs." These devices soon became obsolete with the development of positive-pressure ventilators during the 1950s. The advent of positive-pressure ventilation ushered in the era of modern-day surgery, anesthesia, and critical care medicine.

Mechanical ventilators assist in the oxygenation and ventilation of patients. Ventilators improve pulmonary gas exchange and aim to reverse hypoxemia and acute respiratory acidosis. Mechanical ventilation also unloads the respiratory muscles and therefore significantly decreases the body's oxygen consumption in both shock and respiratory failure. Although positive-pressure ventilation can aid in pulmonary mechanics, it can also lead to ventilator-induced lung injury if improperly applied.

## CLASSIFICATION OF MECHANICAL VENTILATION

All modern ventilators use positive-pressure ventilation. Positive-pressure ventilation can be administered noninvasively (e.g., bilevel positive airway pressure [BiPAP] or continuous positive airway pressure [CPAP] machines); however, this chapter focuses on positive-pressure ventilation delivered by an endotracheal or tracheostomy tube.

#### **INDICATIONS**

- Inability to protect one's airway
- Hypoxic respiratory failure
- Hypercapnic respiratory failure
- Cardiac arrest

#### **CONTRAINDICATIONS**

Advanced directives specifying no intubation or resuscitation are the contraindications for mechanical ventilation.

#### **EQUIPMENT AND SUPPLIES**

- Ventilator
- Ballard suction catheter
- Suction canister and suction tubing
- Yankauer suction tip
- Bite block or oral airway
- Heat and moisture exchanger
- Ventilator circuit tubing
- Metered-dose inhaler adapter
- Bag-valve-mask device

#### **PRECAUTIONS**

 Using inadequate sedation may lead to patient-ventilator dyssynchrony.

- High plateau pressures (>30 cm H<sub>2</sub>O) lead to increased risk of barotrauma (e.g., pneumothorax, pneumomediastinum, pneumopericardium).
- Inadequate head elevation predisposes to ventilator-associated pneumonia.
- High positive end-expiratory pressure (PEEP) levels can decrease cardiac output, leading to hypotension, and can increase intracranial pressure.
- High tidal volume (VT > 10 mL/kg predicted body weight) ventilation may cause ventilator-induced lung injury and acute renal failure.
- Prolonged mechanical ventilation predisposes to
  - Stress gastric ulcers
  - Subglottic stenosis and tracheomalacia
  - Sinusitis
  - Decubitus pressure ulcers
  - Intensive care unit psychosis

#### **TECHNIQUE**

#### **Modes of Ventilation**

There are four main modes of ventilation: controlled mode, assist-control (AC) mode, synchronized intermittent mandatory ventilation (SIMV) mode, and support mode (Table 207-1). Each of these modes is subclassified into volume-cycled or pressure-cycled methods of ventilation.

#### **Controlled Mode**

Controlled ventilation (or intermittent mandatory ventilation) is restricted to use in heavily sedated or paralyzed patients. It is the principal mode of ventilation used for general anesthesia in the operating room. This mode will deliver a preset VT at a specified rate independent of patient effort. The advantage to its use is that the clinician controls with absolute certainty the patient's minute ventilation. However, the disadvantage is that heavy sedation is required to prevent the development of patient–ventilator dyssynchrony.

#### **Assist-Control Mode**

Assist-control ventilation is capable of both assisted ventilation and controlled ventilation. If patients are spontaneously breathing, the ventilator will synchronize with a patient-initiated breath and thereby assist ventilation. If the patient fails to initiate a breath within a given time (as determined by the preset ventilator rate), the machine will provide a controlled breath. AC mode can be volume-cycled (volume control), pressure-cycled, (pressure control), or a hybrid of the two (pressure-regulated volume control).

With volume control (VC) ventilation, each AC breath delivers a preset VT. In other words, both *assisted* breaths and *controlled* breaths receive a preset VT regardless of the pressure required. The machine ensures that the patient will receive a minimum number of breaths per minute, based on the set ventilator rate, even in the

TABLE 207-1 Modes of Ventilation									
Controlled	Assist-Control	Synchronized Intermittent Mandatory Ventilation	Support						
Pressure of volume preset	Pressure of volume preset	Usually volume preset	Usually pressure preset						
Use in paralyzed patient	Use as an initial ventilatory mode	Use in spontaneously breathing patient	Use only in spontaneously breathing patient with adequate respiratory drive						
Patient receives mandatory preset ventilator rate	Patient receives mandatory preset ventilator rate	Patient receives mandatory preset ventilator rate	Patient receives no mandatory preset ventilator rate						
All breaths are ventilator initiated	All spontaneous breaths are ventilator assisted	Spontaneous breaths are not ventilator assisted	All spontaneous breaths are ventilator assisted						
No spontaneous breathing problems		Can be used as a weaning mode	Can be used as a weaning mode						

From Lapinsky SE, Slutsky AS: Ventilator management. In Wachter RM (ed): Hospital Medicine, 2nd ed. Philadelphia, Lippincott Williams & Wilkins, 2005, pp 173–182, Figure 23.1.

absence of patient effort. An advantage is that this mode requires less patient sedation. However, AC cannot limit the respiratory rate of patients who have a high spontaneous respiratory rate. Patients with obstructive lung disease (e.g., chronic obstructive pulmonary disease [COPD], status asthmaticus) and a rapid respiratory rate may develop air trapping. Air trapping can cause auto-PEEP and potentially barotrauma.

With pressure control (PC) ventilation, the ventilator delivers gas at a flow rate necessary to achieve a preset peak pressure. As in VC, the ventilator synchronizes with patient effort, when present, and ensures a minimum ventilatory rate. In PC ventilation the peak inspiratory pressure (PIP) remains constant, but its major disadvantage is that the VT varies from breath to breath depending on the dynamic lung compliance; therefore, the VT can fall to very low levels if the lungs are stiff, which can compromise the minute ventilation.

Pressure-regulated volume control (PRVC) is a hybrid between VC and PC. PRVC is essentially a volume-cycled mode of ventilation with gas flow characteristics similar to those of PC ventilation. The ventilator will deliver a preset tidal volume with each breath using a decelerating flow curve. PRVC allows the delivery of a preset VT at lower peak and mean airway pressures compared with VC.

The primary disadvantage for all modes of AC ventilation is the potential for developing auto-PEEP. At the same minute ventilation, auto-PEEP occurs with fairly equal frequency in VC, PC, and PRVC. See the discussion of auto-PEEP, later, for more details.

#### Synchronized Intermittent Mandatory Ventilation Mode

Synchronized intermittent mandatory ventilation is a mode of ventilation that ensures a preset minimum number of "machine breaths" while allowing spontaneous patient breaths in between. The ventilator waits for a preset time, allowing the patient to breathe spontaneously, and then delivers a "machine breath" synchronized with patient inspiratory effort. The main difference between the AC and SIMV modes is that every breath in the AC mode is ventilator assisted, whereas only a minimum number of breaths per minute are ventilator assisted in SIMV. SIMV can be administered in VC, PC, or PRVC mode; therefore, the ventilator mode can be set as SIMV/VC, SIMV/PC, or SIMV/PRVC. If necessary, pressure support (PS) or PEEP can be added to assist spontaneous breathing in the SIMV mode.

#### Pressure Support Mode

The PS mode is used solely for spontaneously breathing patients. All breaths in this mode are patient-initiated breaths and can be augmented by varying degrees of PS. The least amount of PS that should be added is 6 to 10 cm  $H_2O$  to overcome the resistance of the endotracheal or tracheostomy tube. Higher PS levels

may be applied to aid respiratory mechanics and achieve an adequate VT.

#### **Ventilator Settings and Terminology**

- Inspiratory time: The inspiratory time (I<sub>T</sub>) can be adjusted to change the inspiratory–expiratory (I:E) time ratio. The normal I:E ratio is 1:2. A decreased I<sub>T</sub> is often helpful for conditions requiring a prolonged expiratory time, such as severe bronchospasm (e.g., COPD, asthma exacerbations). An increased I<sub>T</sub> may be indicated for severe hypoxia refractory to high PEEP levels. A significantly prolonged I<sub>T</sub> is usually very uncomfortable, typically requires heavy sedation, and may lead to auto-PEEP.
- Triggering sensitivity: The triggering sensitivity is the amount of negative pressure/flow needed to trigger a ventilator-assisted breath. This is set in all ventilator modes while watching patient effort. The aim is to achieve optimal patient comfort.
- Positive end-expiratory pressure: PEEP is applied by regulating the pressure in the expiratory limb of the ventilator circuit. The goal of PEEP is to keep the alveoli open after expiration to increase the surface area available for gas exchange. In addition, PEEP can recruit lung volume by opening closed alveoli; it also raises intrathoracic pressure, which can decrease cardiac preload. High levels of PEEP (>10 cm H<sub>2</sub>O) can improve oxygenation so that lower levels of inspired oxygen (FiO<sub>2</sub>) can be administered. Furthermore, a high level of PEEP is often needed during lung-protective ventilation in patients ventilated either for acute respiratory distress syndrome (ARDS) or for acute lung injury. PEEP must be used with extreme caution in shock states or if there is any evidence of increased intracranial pressure because high levels of PEEP can worsen both of these conditions.
- Auto-PEEP: Auto-PEEP occurs when there is inadequate time for expiration. It causes an increase in the functional residual capacity and raises intrathoracic pressure, increasing the risk of barotrauma. Volume-cycled AC modes have a higher risk of auto-PEEP compared with the SIMV modes of ventilation. Additional risk factors include severe bronchospasm, high respiratory rates, and a high I:E time ratio.
- Tidal volume: A preset VT is used for all volume-cycled modes of ventilation (VC or PRVC). The ventilator displays both an inspiratory VT and an expiratory VT, which should be the same unless the circuit is occluded or has a leak. VT should be monitored closely when ventilating in PS mode.
- Peak inspiratory pressure: The PIP is the maximal airway pressure
  experienced by the patient. The PIP is a measure of dynamic lung
  compliance and is a pressure preset in PC mode. The PIP levels
  vary in volume-cycled ventilation depending on the breath-tobreath changes in dynamic lung compliance. Causes of a high PIP
  are described later in the discussion of high airway pressures in
  the Ventilator Complications section.

- Plateau pressure: The plateau pressure (PPLAT) is the airway pressure measured after an end-inspiratory hold. This pressure reflects the static lung compliance and is a barometer for the risk of barotrauma. Every effort should be made to keep the PPLAT 30 cm H<sub>2</sub>O or less. A patient with a high PPLAT may require a lower VT (if ARDS), increased sedation (if patient-ventilator dyssynchrony), loop diuretics (if congestive heart failure), or an investigation for abdominal compartment syndrome or pneumothorax.
- Fraction of inspired oxygen: The FIO<sub>2</sub> can vary from 0.21 (room air) to 1.0. The initial ventilator settings typically start with an FIO<sub>2</sub> between 0.8 and 1.0 until adequate oxygenation is ensured. Prolonged administration of an FIO<sub>2</sub> greater than 0.6 can lead to oxygen toxicity through formation of oxygen free radicals; therefore, every effort is made to wean the FIO<sub>2</sub> level down to at least 0.6 as quickly as possible.

#### **Initiating Mechanical Ventilation**

The steps involved in the initiation of mechanical ventilation and required monitoring are outlined in Box 207-1. The initial mode of ventilation is usually the AC mode.

#### Box 207-1. Initiating Mechanical Ventilation

- 1. Choose the mode of ventilation
  - AC if very limited patient effort or heavy sedation (VC or PRVC)
  - SIMV if some respiratory effort or patient–ventilator dyssynchrony on AC
- 2. Settings for oxygenation
  - Initial FIO<sub>2</sub> 0.8 to 1.0, adjust according to SaO<sub>2</sub>
  - Initial PEEP 5 cm H<sub>2</sub>O, adjust according to FIO<sub>2</sub>
  - Aim for SaO<sub>2</sub> ≥90%, PaO<sub>2</sub> ≥60 mm Hg
  - Aim to titrate FIO<sub>2</sub> ≤0.6
- 3. Settings for ventilation
  - Tidal volume: 6 to 10\* mL/kg predicted body weight
  - Ventilator rate: 12 to 16/min, adjust based on PaCO<sub>2</sub> and pH (consider initial rate of 20 to 24 in ARDS)
  - Keep plateau pressure ≤30 cm H<sub>2</sub>O
- 4. Additional ventilator settings
  - Triggering sensitivity: adjust to minimize patient effort
  - I:E ratio: initially 1:2, decrease inspiratory time for severe bronchospasm and can increase inspiratory time for refractory hypoxia
  - Pressure support: if SIMV mode, can adjust between 6 to 20 cm H<sub>2</sub>O titrated to patient comfort
- 5. Monitoring
  - Continuous cardiopulmonary monitor
  - Ventilator: tidal volume, minute volume, airway pressures, serial arterial blood gases
  - ETCO<sub>2</sub> monitors desirable for ventilator weaning

AC, assist-control; ARDS, acute respiratory distress syndrome; ETCO<sub>2</sub>, end-tidal carbon dioxide; FIO<sub>2</sub>, fraction of inspired oxygen; I:E, inspiratory–expiratory time ratio; PaCO<sub>2</sub>, partial pressure arterial carbon dioxide; PaO<sub>2</sub>, partial pressure arterial oxygen; PEEP, positive end-expiratory pressure; SaO<sub>2</sub>, arterial oxygen saturation; SIMV, synchronized intermittent mandatory ventilation; VC, volume control; PRVC, pressure-regulated volume control. \*Desire tidal volume 6 to 8 mL/kg predicted body weight. Adapted from Lapinsky SE, Slutsky AS: Ventilator management. In Wachter RM (ed): Hospital Medicine, 2nd ed. Philadelphia, Lippincott Williams & Wilkins, 2005, pp 173–182, Figure 23.2.

#### Rules of Thumb for Mechanical Ventilation

 Adjust ventilation by changing minute volume, to modify the partial pressure of arterial carbon dioxide (PacO<sub>2</sub>) and pH:

Minute volume = respiratory rate  $\times$  tidal volume (liters)

- Methods to improve oxygenation are as follows:
  - Increase FIO<sub>2</sub> or PEEP first.
  - Increase the I<sub>T</sub> for refractory hypoxia.
- Keep PPLAT no greater than 30 cm H<sub>2</sub>O.
- Avoid ventilating with VT greater than 10 mL/kg (predicted body weight [PBW]).
  - Typical VT is 6 to 8 mL/kg (PBW).
  - PBW for men (kg) =  $50 + (2.3 \times [height in inches 60])$ .
  - PBW for women (kg) =  $45.5 + (2.3 \times [height in inches 60])$ .
- Avoid paralytics (if possible) because of concerns over critical illness polyneuropathy.
- Sedation during mechanical ventilation should include agents that provide anxiolysis, analgesia, and, ideally, amnesia. Sedation should be titrated to an accepted sedation scale (e.g., the Ramsey scale) and continuous sedation should be interrupted on a daily basis.
  - Opiate and benzodiazepine combination.
  - Opiate and propofol combination.
  - Ketamine and benzodiazepine combination.

#### Weaning from Mechanical Ventilation

Weaning from mechanical ventilation involves the transition from full ventilatory support to spontaneous breathing, and then to eventual extubation (Fig. 207-1). There have been numerous approaches to ventilator weaning, but none as successful as daily spontaneous breathing trials (SBT). Patients who pass an SBT can be successfully extubated 85% of the time.

Patients should be assessed on a daily basis as to whether they are ready for an SBT; in part, this consists of clinicians interrupting continuous sedation on a daily basis. Patients should meet the following criteria to be ready for an SBT: (1) awake, cooperative, and able to follow commands; (2) clinically stable and preferably off vasopressor medications; (3) the underlying disease leading to intubation has sufficiently resolved; (4) good gag reflex and a strong cough; (5) minimal pulmonary secretions; (6) spontaneous respirations with a PEEP less than 5 to 8 cm H<sub>2</sub>O; (7) a partial pressure of arterial oxygen (PaO<sub>2</sub>)/FiO<sub>2</sub> ratio of at least 150 to 200; (8) a pH of at least 7.25; and (9) a rapid shallow breathing index (RSBI) of less than 105. The RSBI is checked by placing the patient on CPAP of 5 cm H<sub>2</sub>O with a PS of 0 cm H<sub>2</sub>O for 3 minutes and determining the average respiratory rate divided by the VT (in liters). Patients who have an RSBI greater than 105 fail an SBT 95% of the time.

If the aforementioned criteria are met, an SBT should be performed daily. An SBT can be performed with the patient either on a CPAP level of 5 cm H<sub>2</sub>O and PS of 6 to 8 cm H<sub>2</sub>O or on a T-piece with an FIO<sub>2</sub> no greater than 0.4 to 0.5. Watch the patient for 30 to 120 minutes and terminate the SBT if the patient develops any of the following signs of intolerance: respiratory rate greater than 35/min, arterial oxygen saturation (SaO<sub>2</sub>) less than 90%, PaO<sub>2</sub> less than 60 mm Hg, heart rate greater than 140/min, systolic blood pressure greater than 180 mm Hg or less than 90 mm Hg, agitation, diaphoresis, increased work of breathing, or a VT less than 325 mL (or less than 4 mL/kg PBW). After 30 to 120 minutes, an arterial blood gas can be drawn to ensure adequate oxygenation and ventilation. A PaCO<sub>2</sub> greater than 50 mm Hg (or a greater than 10 mm Hg increase) or a PaO2 less than 55 mm Hg (on  $FIO_2 = 0.4$ ) would be additional reasons to continue mechanical ventilation.

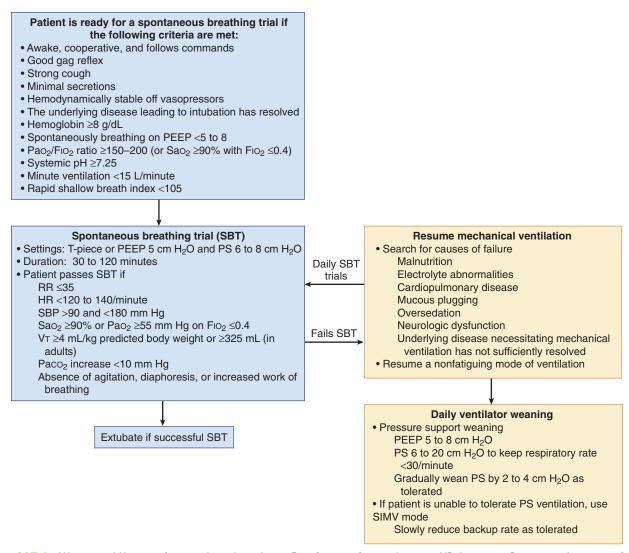

Figure 207-1 Weaning and liberation from mechanical ventilators. FIO<sub>2</sub>, fraction of inspired oxygen; HR, heart rate; PaCO<sub>2</sub>, partial pressure of arterial carbon dioxide; PaO<sub>2</sub>, partial pressure of arterial oxygen; PEEP, positive end-expiratory pressure; PS, pressure support; RR, respiratory rate; SaO<sub>2</sub>, arterial oxygen saturation; SBP, systolic blood pressure; SIMV, synchronized intermittent mandatory ventilation; VT, tidal volume. #### **VENTILATOR COMPLICATIONS**

- High airway pressures: A high airway pressure can be divided into conditions associated with a high PIP or conditions associated with a high PPLAT. The conditions associated with a high PIP, but an unchanged PPLAT, include aspiration, bronchospasm, or endotracheal tube obstruction (kinking or secretions). Conditions that have an elevation in both the PIP and PPLAT include "bucking the ventilator," pulmonary edema, pneumothorax, auto-PEEP, severe abdominal distention, ARDS, or chest wall noncompliance. "Bucking the ventilator" may be caused by inadequate sedation, paroxysms of coughing, or patient-ventilator dyssynchrony.
- Barotrauma: Barotrauma is defined as lung injury due to high mean airway pressures. It occurs when there is an alveolar leak causing one of the following clinical conditions: pneumomediastinum, pneumopericardium, pneumothorax, or subcutaneous emphysema. Those at highest risk for barotrauma have one of the following conditions: very stiff lungs (e.g., in ARDS); severe bronchospasm; PPLAT greater than 30 cm H<sub>2</sub>O; use of a high I<sub>T</sub>; the development of auto-PEEP; and VT greater than 10 mL/kg PBW.

- Low airway pressures: A low airway pressure usually means a leak in the ventilator circuit. This can be caused by the patient becoming disconnected from the ventilator, a loose tubing connection, or a large cuff leak.
- Hypotension: The causes of hypotension in a ventilated patient
  can be divided into ventilator-related causes, patient-related
  causes, and medication-induced hypotension. The ventilatorrelated causes include high PEEP levels, the development of
  auto-PEEP, or a tension pneumothorax. Patient-related causes
  include hypovolemia, a worsening shock state (e.g., septic, cardiogenic, anaphylactic), abdominal compartment syndrome, a
  massive pulmonary embolus, unstable arrhythmia, or a massive
  myocardial infarction. Finally, medication-induced hypotension
  may be caused by excessive sedation (e.g., opiates, propofol, benzodiazepines), medication hypersensitivity response, or the excessive use of antihypertensives.
- Reversible causes of hypoxia: The reversible causes of hypoxia in a ventilated patient can be remembered by the mnemonic CDSPIES (Box 207-2). Causes of chronic hypoxia are not included as etiologies. Splinting applies only to spontaneous breathing in a support mode when the VT is limited by pain.

#### Box 207-2. Reversible Causes of Hypoxia in Ventilated Patients

- C Congestive heart failure
- D Drugs (oversedation leading to hypoventilation in spontaneously breathing patients)
- Secretions or splinting (leading to atelectasis in spontaneously breathing patients)
- Pneumothorax
- Infection (ventilator-associated pneumonia)
- E Embolism (pulmonary embolism)
- S Spasm (bronchospasm)
- High respiratory rates: The most common causes of a high respiratory rate in a ventilated patient are inadequate sedation, hypoxia, and anxiety. Other causes include a profound metabolic acidosis with a compensatory stimulus to hyperventilate, neurogenic hyperventilation, a pulmonary embolus, and toxic overdoses that stimulate the medullary respiratory center (e.g., salicylate overdose).
- Apnea: The most common cause of apnea in a ventilated patient is oversedation or the use of paralytics. Other potential causes include a central nervous system catastrophe or central sleep apnea.
- Ventilator-induced lung injury: Ventilator-induced lung injury results either from shear stress or from overdistention injury. Shear stress is caused by the repetitive opening and collapsing of alveoli. Overdistention injury results from the prolonged application of high-VT ventilation (VT >10 mL/kg PBW). Overdistention injury is especially common if there are areas of normal and diseased lung; the normal lung will be preferentially ventilated and therefore is at risk of overinflation. Conditions associated with poor lung compliance, like ARDS, are at highest risk for ventilator-induced lung injury, and therefore are indications for the use of lung-protective ventilation (Table 207-2).
- Self-extubation: Self-extubation can occur for several reasons. First, it can be the inadvertent consequence of moving the patient without adequate attention to the airway. It can also occur as a result of inadequate sedation or loose restraints in an agitated patient.
- Decubitus pressure ulcers: Patients who have been mechanically ventilated for a prolonged period are at risk for development of

- pressure ulcers of the occiput, sacrum, and heels. Frequent turning is imperative.
- Venous thromboembolism: Mechanical ventilation is a risk factor for venous thromboembolism. All ventilated patients should receive prophylactic heparin or sequential compression stockings to minimize the risk of a deep venous thrombosis.
- Stress gastric ulcers: Mechanical ventilation for longer than 48 hours places patients at risk for a stress ulcer. Therefore, histamine type 2 blockers or proton pump inhibitors should be administered as prophylaxis against the development of a stress gastric
- Ventilator-associated pneumonia: Patients who have required mechanical ventilation for longer than 48 hours are at risk for a ventilator-associated pneumonia. The risk of ventilator-associated pneumonia can be decreased by performing the following interventions: raise the head of the bed to 45 degrees, avoid gastric overdistention, minimize ventilator circuit changes/manipulation, drain ventilator circuit condensate on a regular basis, use appropriate hand disinfection before patient care, consider kinetic bed therapy for prolonged mechanical ventilation, and administer twice-daily oral care with chlorhexidine rinses. Selective gut decontamination has a role in trauma patients. Other promising interventions include endotracheal tubes with either low-volume/ high-compliance cuffs or those that allow for continuous subglottic suctioning.

#### POSTPROCEDURE MANAGEMENT

- Check a daily chest radiograph in all endotracheally intubated patients.
- Assess ventilator settings frequently and adjust accordingly.
- Ensure the patient is receiving interventions to prevent decubitus ulcers, gastric ulcers, a ventilator-associated pneumonia, or a deep venous thrombosis and assess daily for vent complications.
- Assess patients daily for potential to wean or discontinue ventilatory support.

#### **CPT/BILLING CODES**

94003 Ventilation assist and management; hospital inpatient/ observation, subsequent days

#### Protocol for Lung-Protective Ventilation **TABLE 207-2**

- 1. Assist-control mode with  $FIO_2 = 100\%$
- 2. VT = 8 mL/kg predicted body weight (PBW)

PBW for men (kg) =  $50 + [2.3 \times (height in inches - 60)]$ 

PBW for women (kg) =  $45.5 + [2.3 \times (height in inches - 60)]$ 

Decrease VT I mL/kg PBW every I to 2 hr until VT = 6 mL/kg PBW

- 3. Initial respiratory rate typically 12 to 16/min, but can increase up to 35/min
- 4. Initial PEEP 5 to 8 cm H<sub>2</sub>O, and adjust based on PEEP-FIO<sub>2</sub> algorithm (see below)
- 5. Adjust PEEP and FiO2 to keep  $PaO_2 > 55$  mm Hg or  $SaO_2 > 88\%$
- 6. Decrease VT as low as 4 mL/kg PBW if PPLAT > 30 cm H<sub>2</sub>O despite adequate suctioning and sedation
- 7. Allow permissive hypercapnia and may use sodium bicarbonate to keep pH > 7.15

### PEEP-FIQ. Algorithm for Lung-Protective Ventilation

# ARTERIAL PUNCTURE AND PERCUTANEOUS ARTERIAL LINE PLACEMENT

Grant C. Fowler • Donna A. Landen

#### **ARTERIAL PUNCTURE**

An arterial puncture can be useful in certain urgent, acute, or chronic conditions, basically whenever an arterial blood sample is needed. If frequent sampling or (intra)arterial blood pressure monitoring is necessary, placement of an arterial line should be considered. With proper technique and equipment, an arterial puncture is a safe and simple procedure. However, advancements in technology for noninvasive monitoring may eventually make this procedure obsolete. Use of pulse oxymetry (arterial oxygen saturation) and end-tidal CO<sub>2</sub> (ETCO<sub>2</sub>) monitoring has already markedly decreased the need for arterial puncture. In most cases, an arterial puncture is used now only to assess and confirm hypoxia or hypercapnia when indicated by pulse oxymetry or ETCO<sub>2</sub> monitoring. Although venous sampling may occasionally be used to monitor pH (e.g., diabetic ketoacidosis), venous blood pH is much less reliable as a surrogate marker for arterial pH in patients with shock and other critical illnesses; therefore, arterial puncture is still necessary in these patients.

#### **Indications**

- To confirm a clinically suspected acute problem with carbon dioxide or oxygen exchange, or with acid-base balance, such as patients with shock, asthma exacerbation, chronic obstructive pulmonary disease (COPD) exacerbation, pulmonary thromboembolism, diabetic ketoacidosis, or refractory cardiac dysrhythmias, or patients who are either newly comatose or have a depressed level of consciousness.
- To confirm the clinical status in a patient with a chronic condition that affects gas exchange or acid-base balance, such as chronic COPD. Long-term continuous oxygen therapy has proven beneficial (e.g., decreased mortality and hospitalizations) in patients with COPD with a partial pressure of arterial oxygen (PaO<sub>2</sub>) less than 59 mm Hg (especially with comorbid disease, e.g., cor pulmonale, pulmonary hypertension), and even more if the PaO<sub>2</sub> is less than 55 mm Hg.
- To confirm hypoxia when pulse oximetry may not be reliable or is not available or obtainable (e.g., patient with severe hypoxia or severe hypotension).
- To confirm hypoxia, when pulse oximetry suggests this diagnosis.
- To confirm hypercapnia when ETCO<sub>2</sub> monitoring may underestimate (e.g., patient with large dead space ventilation or low cardiac output).
- To confirm the need for long-term continuous oxygen therapy. Medicare requires at least two blood gas determinations, while breathing room air for 20 minutes, with PaO<sub>2</sub> less than 59 mm Hg (with cor pulmonale, clinically diagnosed, or hematocrit ≥55%)

- or  $PaO_2$  less than 55 mm Hg, to qualify for continuous oxygen therapy, or, alternatively, after 20 minutes of breathing room air and using pulse oximetry, two oxygen saturation readings  $\leq 88\%$ . The company providing the oxygen cannot be the same company that does the blood gas testing in the home.
- To obtain arterial blood for certain laboratory tests (lactate, ammonia, carboxyhemoglobin, methemoglobin, or carbon monoxide levels, although some laboratories can use venous blood).
- To obtain a blood sample in an emergent situation when phlebotomy cannot be performed or when there are no venous sites.

#### **Contraindications**

- When a functional arterial line is present
- Overlying skin compromised by trauma, burns, infection, severe dermatitis (relative contraindication in life-threatening situation)
- Known or suspected severe arterial disease of aneurysmal, atherosclerotic, inflammatory, or vasospastic nature (relative contraindication in life-threatening situation)
- Previous surgery in the area that may have caused scarring, thereby complicating the procedure (relative contraindication, can always use hand-held Doppler technique)
- Poor collateral perfusion from the ulnar or posterior tibial artery when the radial or dorsalis pedis artery, respectively, is the intended puncture site (may be relative contraindication)
- Inability to palpate arterial pulsation (relative contraindication, can always use hand-held Doppler technique)
- Synthetic vascular graft (relative contraindication)
- Additional relative contraindications: bleeding dyscrasias, anticoagulant therapy, or possible later thrombolytic or fibrinolytic therapy. These patients should be monitored carefully after arterial puncture to prevent complications.

**NOTE:** If drawing of frequent arterial specimens or continuous pressure monitoring is necessary, placement of an arterial line should be considered.

#### **Equipment**

- 3- to 5-mL sterile plastic or glass syringe with a freely movable plunger. (Kits are made in which the preheparinized syringe plunger should not be moved. A lyophilized heparin pellet may be in the syringe. These kits also contain the needle and rubber stopper or syringe plug.)
- 25-gauge, ½-inch (1.6-cm) needle for radial, brachial, dorsalis pedis, and femoral puncture. For femoral puncture in obese patients, a 22-gauge, 1½-inch (3.8-cm) needle may be helpful.

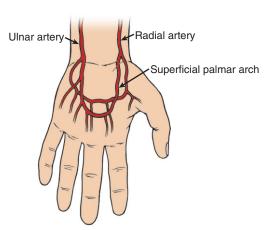

- 1 or 2 mL heparin (1000 U/mL)
- Plug for syringe or rubber stopper for end of needle
- Antiseptic skin preparation, such as povidone-iodine (Betadine) or 70% isopropyl alcohol
- Sterile  $4 \times 4$  gauze pads
- Hypoallergenic adhesive tape
- Container with 2 to 3 inches of crushed ice for sample transport (e.g., plastic bag, emesis basin, cup)
- Sterile gloves
- Equipment for the clinician to observe universal blood and body fluid precautions
- In the alert patient (optional), 1% or 2% lidocaine without epinephrine and a 1- or 3-mL syringe with 25- or 27-gauge, ½-inch (1.6-cm) needle
- Handheld Doppler or pulse oximeter (optional)

#### **Arterial Site Selection**

Each site for arterial puncture has its own risks and benefits. Because of its proximity to the skin surface, the radial artery in the patient's nondominant hand is the preferred site. It is an excellent location if there is adequate ulnar artery collateral circulation (see the following section) and if the clinical situation is stable. In severely hypotensive patients or during cardiopulmonary resuscitation, the femoral artery is usually the most readily palpable and most conveniently located artery, in spite of its higher risk of complications with puncture. Alternative sites, in decreasing order of preference, include the brachial, dorsalis pedis, and superficial temporal arteries. The brachial artery should be reserved for use when radial artery puncture cannot be performed or is contraindicated. Although the dorsalis pedis artery is absent, usually bilaterally, in 12% of the population, it is another option for puncture. Before dorsalis pedis artery puncture is performed, collateral flow should be demonstrated in a manner similar to the Allen test (see the following section). Superficial temporal artery puncture will not be discussed. Ultimately, clinician experience and local anatomy are the deciding factors in choice of site. If possible, the clinician should avoid an artery where the overlying cutaneous defenses are disrupted because of infection, burn, severe dermatitis, or other skin damage.

#### Assessment of Ulnar Collateral Circulation

Radial artery puncture can lead to thrombosis of the distal artery. Because 12% of hands have inadequate collateral flow because of an incomplete palmar arch (Fig. 208-1), to minimize the risk of permanent ischemic damage to the hand, many experts suggest confirming adequate collateral circulation before puncture. Even if there is excellent collateral flow, the nondominant hand should be used, if

**Figure 208-I** Anatomy of radial and ulnar arteries at wrist and superficial palmar arch.

possible. However, other experts have questioned the value of testing for collateral circulation. At least one large case series of patients demonstrated the safety of radial artery cannulation without testing for collateral circulation with the modified Allen test in patients without major peripheral arterial disease (Slogoff and colleagues, 1983).

**MODIFIED ALLEN TEST.** The Allen test, used to evaluate ulnar collateral flow, was first described in 1929. To minimize falsely abnormal results, the modified Allen test can be used:

- 1. The hand should be at least room temperature (>70° F). It can be warmed in water, if necessary. The patient should hold his or her arm above heart level, and then open and close the hand several times to exsanguinate it. Next, the patient should clench the fist tightly. The clinician then compresses both the radial and ulnar arteries (Fig. 208-2A). (In a comatose or anesthetized patient, the hand can be elevated and clenched passively by an assistant.)
- 2. After a minute is allowed for blood to drain from the hand, the fist should be lowered below the level of the heart, unclenched (Fig. 208-2B), and pressure on the ulnar artery (Fig. 208-2C) released. Care should be taken to avoid hyperextension of the wrist or fingers, which can lead to a falsely abnormal test result. When the pressure on the ulnar artery is released, the cadaveric color of the entire hand should return to its normal color within 6 seconds (Fig. 208-2D). Color usually returns to the palm first, and then to the entire hand. If any area of the hand does not rapidly (within 6 seconds) return to normal color, this is a positive modified Allen test. The thumb, index finger, and thenar eminence are the areas most commonly involved in a positive test. These areas often have inadequate collateral blood flow and may be entirely dependent on the radial artery for perfusion.

An abnormal or equivocal modified Allen test result, although it may not preclude arterial puncture or cannulation, should alert the clinician to potential complications, a need for caution when performing the procedure, and a need to monitor the patient closely postprocedure. Various types of noninvasive studies are also useful for further patient evaluation. Hand-held Doppler ultrasonography or pulse oximetry can be used to rapidly assess perfusion with techniques more sensitive and specific than the modified Allen test. If time allows, formal arterial Doppler ultrasonography, either portable or in the radiology department, can be used to further evaluate the collateral circulation or direct the puncture.

#### HAND-HELD DOPPLER EVALUATION

- 1. After placing the probe between the heads of the third and fourth metacarpals on the palm, angulate the probe and advance it proximally until maximal auditory signal is obtained (Fig. 208-3).
- 2. With the palmar arch identified and maximal signal obtained, compression of the radial artery should not cause a change of the signal if the palmar arch is complete and supplied by collateral ulnar circulation. A decrease in signal indicates poor collateral flow. This is a much more sensitive and specific test than the modified Allen test.

**PULSE OXIMETRY EVALUATION**. This is especially useful in the unconscious patient.

- 1. Place the sensor of a pulse oximeter with a visual pulse waveform display on the patient's thumb.
- While examining the waveform on the monitor, occlude the radial artery. If the waveform remains unchanged after radial artery occlusion, the patient has adequate collateral circulation, probably from the ulnar artery.

#### Assessment of Dorsalis Pedis Collateral Circulation

To minimize the risk of permanent ischemic damage to the distal foot, some experts suggest confirming adequate collateral circulation before dorsalis pedis artery puncture is attempted.

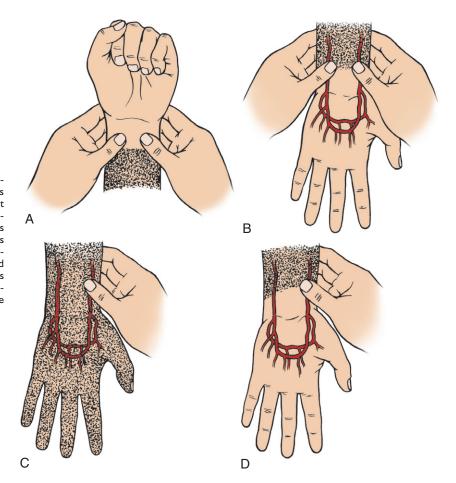

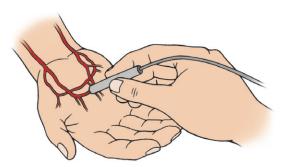

Figure 208-2 Modified Allen test. A, Hand is elevated and fist clenched while radial and ulnar arteries are occluded for I minute. B, Hand is lowered and fist is unclenched. Hand is cadaveric. C, Ulnar artery compression is released while radial artery compression is continued. In a negative test, the entire hand regains color within 6 seconds. D, Positive test. With inadequate collateral perfusion from the ulnar artery, the hand remains cadaveric as long as radial artery compression is maintained. When inadequate collateral perfusion is demonstrated, another puncture or cannulation site should be considered.

- 1. The foot should be at least room temperature (>70° F). It can be warmed in water, if necessary.
- 2. After locating and palpating the dorsalis pedis artery (Fig. 208-4), occlude it with compression.
- 3. Blanch the great toenail by compressing for several minutes.
- 4. Release pressure on the nail and observe for flushing. A rapid return of color indicates adequate collateral flow.

**NOTE:** In most persons, collateral circulation of the foot is provided by a branch of the posterior tibial artery. Hand-held Doppler ultrasonography can be used to assess collateral flow between the dorsalis pedis and posterior tibial arteries in a manner similar to that used in the palmar arch.

#### **Preprocedure Patient Preparation**

The clinician and patient should be in a comfortable position that can be maintained for 10 to 15 minutes. The procedure, its necessity, alternatives (if there are any), and possible complications should be explained to the alert patient. In nonemergent situations, informed consent should be obtained (see the sample patient consent form online at www.expertconsult.com). The patient should be prepared for some discomfort.

**Figure 208-3** Assessment of the superficial palmar arch with hand-held Doppler ultrasonography.

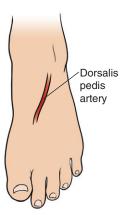

Figure 208-4 Location of the dorsalis pedis artery.

#### **Technique**

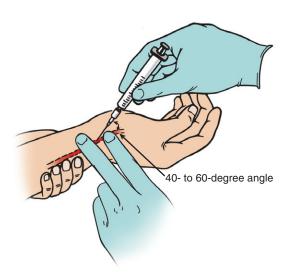

1. Rinse the syringe with a small amount (1 or 2 mL) of heparin and then empty it through the needle. For glass syringes, this step not only coats the syringe with heparin, it eliminates the dead space in the syringe and needle. Although heparin does not adhere to plastic syringes, performing this step with plastic syringes will displace any air and fill the dead space.

**NOTE:** Certain kits contain syringes that are already heparinized (often containing a pellet of lyophilized heparin) and the plunger should not be moved.

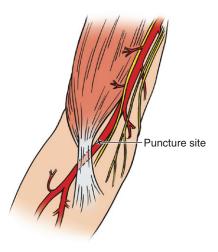

- 2. Following universal blood and body fluid precautions, prepare the skin in an aseptic manner and put on sterile gloves.
- 3. The clinician should use his or her nondominant hand to palpate the selected artery with the balls of two or three fingers, and immobilize it with these fingers along its course.
- 4. Optional: Local anesthetic (lidocaine) can be injected for a particularly anxious patient to minimize hyperventilation artifact. However, use minimal amounts to avoid anatomic distortion, which could make it difficult to palpate and puncture the pulse.
- 5. Holding the barrel of the syringe like a pencil in the dominant hand, keep the needle bevel up.
- 6. Depending on the site selected, perform the puncture.
  - Radial artery puncture: Dorsiflex the supine wrist (about 30 degrees) of the patient's nondominant hand and rotate it outward (externally), slightly. The wrist should be supported by a firm surface, such as an assistant's hand, a rolled towel or washcloth, or a 500-mL intravenous (IV) fluid bag. Insert the needle where the pulse is most prominent—½ to 1 inch proximal to the wrist crease—at a 40- to 60-degree angle to the skin. Direct it slowly in the long axis of the artery toward the pulsation (Fig. 208-5).

**NOTE:** Avoid "spearing" (going through) the artery. Osteomyelitis and large hematomas can result from "spearing" the artery.

 Brachial artery puncture: Place the patient's elbow on a rolled towel or washcloth. Slightly hyperextend and supinate the arm (palm up) with the patient's wrist in the anatomic position but rotated slightly outward. The brachial artery pulsation should be palpable in the medial aspect of the

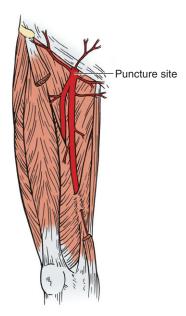

**Figure 208-5** This patient is left-hand dominant. Palpate the patient's radial pulse with your left hand. While holding the heparinized syringe with your right hand (reverse hands if left-handed), puncture the skin at approximately a 60-degree angle to the skin, directing the needle toward the radial pulsation.

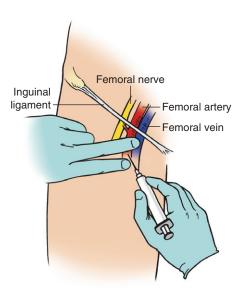

**Figure 208-6** Right brachial artery and its branches, and the anatomic site for brachial artery puncture.

antecubital fossa (Fig. 208-6), lateral to the medial epicondyle, but medial to the biceps tendon. Insert the needle at about a 45- to 60-degree angle, slightly above the elbow crease, in the antecubital fossa or slightly proximal to it. Aim along the long axis of the artery toward the pulsation.

- Femoral artery puncture (Fig. 208-7): With the patient in a supine position and legs straight, rotated slightly outward, insert the needle 1 to 1½ inches distal to the inguinal ligament at about the inguinal crease. It should be at a 60- to 90- degree angle to the distal skin and aimed toward the pulsation (Fig. 208-8). Avoid puncturing lateral to the pulsation because the femoral nerve could be damaged.
- Dorsalis pedis artery puncture (Fig. 208-9): With the patient in a supine position, insert the needle where the pulse is most prominent, at a 45- to 60- degree angle to the sole of the foot. Aim toward the pulsation.
- 7. Although penetration into the artery can occasionally be sensed, puncture is usually detected when blood enters the syringe. It should enter the syringe spontaneously without with-

**Figure 208-7** Right femoral artery and its branches, and the anatomic site for femoral artery puncture.

**Figure 208-8** Technique of femoral artery puncture. The first two fingers of the free hand are used to palpate the femoral artery.

drawing the plunger if the syringe is specifically designed for arterial puncture. With plastic syringes or in severely hypotensive patients, slight aspiration may be necessary. Otherwise, attempt to avoid aspiration to decrease the chance of obtaining venous blood. If blood is not obtained during the insertion, slowly withdraw the needle and stop when blood appears.

- 8. If no blood appears, withdraw the needle completely and start again. For additional attempts, advance the needle without changing the angle of approach but with the needle directed \( \frac{1}{8} \) inch to either side of the previous attempt.
- 9. When blood appears, collect 3 mL of blood and remove the needle from the artery with a smooth, swift motion while applying pressure to the site. Steady pressure should be maintained for at least 5 minutes (longer in hypertensive patients and patients on anticoagulant therapy).
- 10. While applying pressure at the site with one hand, use the other hand to hold the syringe with the needle tip upright and expel any air bubbles. Tapping the syringe may help expel bubbles clinging to the sides.
- 11. Secure the needle tip by impaling it on a rubber stopper or remove the needle and cap the syringe securely. (Special rubber caps are available for this purpose.) Do not allow any room air to get into the syringe or any air bubbles to remain.

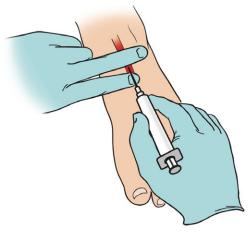

Figure 208-9 Technique of dorsalis pedis artery puncture.

- 12. Roll the syringe between the palms of the hands four or five times to mix the blood uniformly with the heparin.
- 13. Label the syringe appropriately with the patient's name and number(s), and place the syringe on ice. Immediately transport the syringe to the laboratory.
- 14. Return in 10 to 15 minutes and check the puncture site for hematoma formation and for adequate distal perfusion.

#### **Complications**

- Repeated punctures at the same site increase the risk of complications.
- Hemorrhage or hematoma is the most common complication. Risk can be minimized by prompt, continuous application (for 5 to 10 minutes) of pressure after the procedure, and by using a small-gauge (25-gauge) needle, if possible.
- Thrombosis is a possible complication of any arterial puncture. It
  more commonly results from puncture of the radial artery or any
  artery with occlusive disease. The risk increases with repeated
  punctures. For a diminished pulse after puncture, prompt vascular
  surgical consultation should be obtained. Ischemia and resulting
  gangrene are additional possible complications.
- Nerve damage can occur, either from direct needle insertion into the nerve or from the pressure of a resultant hematoma. This is more common with brachial and femoral artery punctures.
- Infection, including septic arthritis from a femoral artery puncture, is a possible complication. Try to avoid puncturing down to the bone with a femoral artery puncture (or any other puncture).
- Pseudoaneurysms have been reported, especially with femoral artery puncture. A pseudoaneurysm appears as a "pulsating tumor," anterior to the artery, often associated with a bruit. These occur more often after resolution of a large hematoma. Treatment is surgical removal of the pseudoaneurysm by a vascular surgeon.
- An arteriovenous fistula may form after femoral puncture. In part, this is why the radial artery is a preferred site because there is no accompanying large vein.
- Spurious laboratory results are most often the consequence of mixing venous blood with the arterial sample, but they can also be due to an excessive quantity of heparin in the syringe. Heparin has a very low pH; therefore, using too much can cause not only a falsely low partial pressure of arterial carbon dioxide (Paco<sub>2</sub>), but a low pH. Delay in analyzing the specimen or improper chilling can cause the blood to metabolize the oxygen, or the oxygen to dissociate from hemoglobin. This will falsely lower the oxygen and pH and falsely elevate the PaCO<sub>2</sub>. Air in the syringe may markedly lower the PaCO<sub>2</sub> because room air contains little carbon dioxide. Depending on whether the initial partial pressure of arterial oxygen (PaO<sub>2</sub>) was greater or less than room air, mixing the sample with air may either falsely lower or elevate the PaO<sub>2</sub>. Vacutainers should not be used to draw arterial blood; even though they are filled with nitrogen, they contain measurable amounts of oxygen. Even this small amount of oxygen will significantly alter the PaO<sub>2</sub>.

#### **Postprocedure Patient Education**

The patient should be instructed to avoid rubbing the site. He or she should report any bleeding, pain, swelling, numbness, or tingling after the arterial puncture. If the extremity turns cold or blue, the patient should inform the nurse or clinician. If the patient is awake and alert, he or she can help hold pressure on the site while the clinician is delivering the specimen to the laboratory.

#### PERCUTANEOUS ARTERIAL LINE PLACEMENT

Intra-arterial procedures are now common, with arterial dye studies and angioplasty even being performed by noncardiologists and nonsurgeons (e.g., interventional radiologists). The most common

intra-arterial procedures performed are arterial puncture and arterial cannulation. If arterial cannulation is to be performed, support staff and facilities must be properly trained and prepared to deal with setup and possible complications, which can be more frequent and severe than with IV cannulation or arterial puncture. The site (radial, femoral, or dorsalis pedis artery) should be chosen according to the same risks and priorities established in the Arterial Puncture section. Benefits of arterial cannulation include accurate arterial pressure measurements, less discomfort and injury than with frequent arterial punctures, and the ability to obtain arterial samples without disturbing the steady state (e.g., pain induced with arterial puncture can cause hyperventilation, resulting in falsely low PaCO<sub>2</sub> measurements).

**NOTE:** For noninvasive monitoring of arterial pressure, Korotkoff sounds are commonly used. With increased wall tension (e.g., in vasoconstricted patients, such as those with increased systemic vascular resistance from shock), the ability of the arterial walls to produce the Korotkoff sounds may be altered. Therefore, in these patients, low cuff pressure does not necessarily indicate hypotension. Relying on Korotkoff sounds alone in such patients can result in dangerous errors in therapy. Stiff walls from atherosclerosis can also alter Korotkoff sounds.

#### **Indications**

- When there is difficulty obtaining or risk of inaccuracy of cuff blood pressure in a critically ill patient
- When continuous monitoring of arterial blood pressure is needed, especially in patients with shock, patients with resultant increased systemic vascular resistance, patients who have the potential to become hemodynamically unstable, and during major surgery or administration of parenteral vasopressor or dilator medications
- With labile or accelerated hypertension and evidence of progressive vascular damage (mean arterial pressure [MAP] is a much more consistent parameter for accelerated hypertension than the systolic or diastolic pressure alone)
- To monitor MAP in patients in whom it is necessary to maintain MAP at a certain level (e.g., to maintain cerebral perfusion pressure in a patient poststroke)
- When continuous access to arterial blood is needed (to avoid repeated arterial punctures)
- To measure cardiac output by the dye dilution method

#### **Contraindications**

#### **Absolute**

- Inadequate collateral blood flow distal to where the arterial line will be placed (e.g., abnormal modified Allen test or dorsalis pedis collateral flow test result, or hand-held Doppler ultrasonography or pulse oximetry reveals inadequate collateral arterial circulation; see the Arterial Puncture section)
- Patients with a significant injury to the same extremity, especially
  if it may compromise distal perfusion
- Hypercoagulable states

#### Relative

The following are relative contraindications; in life-threatening or certain other situations, the benefits of arterial cannulation may outweigh the risks. In some patients, arterial cannulation will decrease the risks of bleeding from multiple punctures.

- Severe atherosclerotic or vasospastic arterial disease
- Local skin compromise, such as with trauma, infection, burn, or severe dermatitis
- Anticoagulation from bleeding disorders, anticoagulant therapy, or potential future thrombolytic therapy
- Synthetic vascular graft

**NOTE:** Although certain experts no longer recommend cannulation of the brachial artery because of the increased potential for thrombosis and ischemia of the lower arm and hand, others prefer brachial artery cannulation to radial or dorsalis pedis artery cannulation in certain patients (e.g., the patient with anasarca). Brachial artery cannulation is also less likely to cause infection than femoral artery cannulation.

#### Equipment

- Sterile gloves, drapes, and  $4 \times 4$  gauze sponges
- Equipment for the clinician to observe universal blood and body fluid precautions
- Antiseptic skin preparation, such as povidone—iodine or chlorhexidine solution
- In the alert patient (optional), 1% or 2% lidocaine without epinephrine and a 3-mL syringe with 25- or 27-gauge, %-inch (1.6-cm) needle
- Short arm board/wrist extensor splint and a rolled gauze, towel, or washcloth, about 3 inches in diameter, for radial artery cannulation; arm board and the same rolled gauze, towel, or washcloth for brachial artery cannulation
- For radial, dorsalis pedis, or brachial artery cannulation, a 20-gauge, 1<sup>1</sup>/<sub>4</sub>- to 2-inch (3.2- to 5.1-cm) Teflon catheter-overneedle with a nontapered shaft
- For femoral artery cannulation, a 19- or 20-gauge or 4-Fr, 6-inch (15- to 16-cm) single-lumen cannula
- For the Seldinger or wire-guided technique, a flexible guidewire small enough to pass through the catheter and needle
- Fluid-filled connector tubing attached to sterile three-way stopcock and transducer (using a stiff, low-capacitance tubing will minimize the artifact; also, attempt to minimize the length of tubing); transducers are available with needleless sampling ports
- Antibiotic ointment, such as povidone-iodine ointment
- Nylon 3-0 or 4-0 suture, preferably on a skin needle
- Hypoallergenic adhesive tape
- Suture scissors
- Bag of sterile dextrose water (D<sub>5</sub>W) IV fluid mixed with heparin to make a 1-U/mL solution for flushing (this should be in-line with the connector tubing)
- Scissors for clipping hair for femoral insertion
- Hand-held Doppler (optional technique)
- No. 11 or no. 15 blade scalpel, mosquito hemostat, and nylon 3-0 suture for cutdown (optional technique)

#### **Preprocedure Patient Preparation**

Explain the indications, complications, and necessity of the procedure to the patient if he or she is alert and awake. If the patient is unconscious, explain this to the next of kin. If there are alternatives available, discuss them as along with the benefits of this procedure. Discuss the importance of immobilization while the procedure is being performed, and warn the patient of the discomfort that will be felt with the insertion of the catheter. Inform the patient that this catheter is more dangerous than an IV catheter and that care must be taken with the catheter after insertion. Obtain written consent for the procedure or document implied consent in the chart if the patient is unconscious.

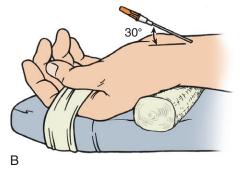

#### **Technique**

- The clinician and the patient should be in a comfortable position that can be maintained as long as necessary to complete the procedure. When using nonclosed systems, observe universal blood and body fluid precautions.
- The clinician should palpate the artery selected and immobilize it along its course with two or three fingers of his or her nondominant hand.

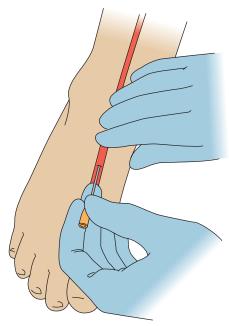

- 3. Prepare the skin in an aseptic manner. For femoral cannulation, use scissors to clip any long hairs in the area of the cannulation.
- 4. Local anesthetic (lidocaine) can be injected for a particularly anxious patient. It may also prevent arterial spasm when the artery is punctured. Use minimal amounts to prevent anatomic distortion, which may make it difficult to palpate the pulse. If the anatomy does get distorted from the anesthetic injection, attempt to massage it into the surrounding skin and soft tissue.
- 5. Drape the area with sterile towels.
- 6. Wearing sterile gloves, the clinician should hold the catheter needle hub like a pencil in his or her dominant hand with the needle bevel up.
- 7. Depending on the site selected, perform the cannulation.
  - Radial artery cannulation: On the patient's selected hand (preferably the nondominant hand), slightly dorsiflex (about 30 degrees), slightly rotate outward, and immobilize the wrist by taping a gauze roll between the supinated wrist and the dorsally applied arm board (Fig. 208-10A). The 3-inch roll should be between the arm and the board. Apply tape over the proximal interphalangeal joints (excluding the thumb) and around the arm board. Also apply tape more proximally, securing the forearm to the arm board. Insert the needle ½ to 1 inch proximal to the wrist crease, at about a 30-degree angle to the distal skin. Direct it slowly down the long axis of the artery toward the pulsation (Fig. 208-10B).
  - Femoral artery cannulation: With the patient in the supine position and legs straight, rotated slightly outward, insert the needle at a 45-degree angle to the skin and direct it toward the patient's head. Also, direct it toward the femoral artery pulsation, 2 to 5 cm distal to the inguinal ligament at the inguinal crease. After the flash of blood, the angle can be lowered to 20 or 30 degrees relative to the distal skin.

**NOTE:** Large hematomas are not uncommon in this area because of the amount of surrounding soft tissue. Femoral artery cannulation also carries the risk of more serious complications. Avoid puncturing proximal to the inguinal ligament, which could cause a retroperitoneal hematoma. The proximity of this location to the groin may increase the risk of infection. This

**Figure 208-10 A,** Position for radial artery cannulation. **B,** Catheter is directed along the long axis of the artery.

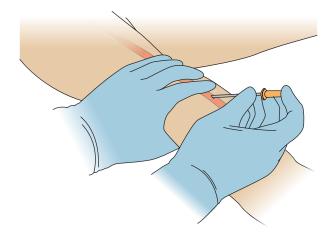

**Figure 208-11** Dorsalis pedis artery cannulation. (Modified from American Heart Association: Textbook of Advanced Cardiac Life Support. Dallas, American Heart Association, 1997.)

location is also less popular for patients if they are awake; they should not ambulate with a femoral artery cannulation in place (see Fig. 208-7).

• Dorsalis pedis artery cannulation: With the patient in the supine position and the foot plantar flexed and stabilized on a firm surface, such as the bed, the dorsalis pedis artery should be palpated and stabilized using sterile technique (Fig. 208-11). Direct the needle tip and catheter slowly along the axis of the artery, aimed toward the arterial pulsation, at a 20- to 30-degree angle to the distal skin.

NOTE: Because collateral circulation in the foot is usually good, dorsalis pedis arterial cannulation should be considered when radial artery cannulation is not a good option. In patients with good cardiac output and palpable dorsalis pedis and posterior tibial pulses, dorsalis pedis arterial cannulation by experienced personnel has been demonstrated to have minimal risk of adverse events such as ischemia and thrombosis. It also allows the patient a little more mobility than with femoral artery cannulation.

- Brachial artery cannulation: With the patient's elbow on a rolled towel or washcloth, slightly hyperextend and supinate the patient's nondominant arm so the patient's wrist lies in the anatomic position but rotated slightly outward. Immobilize the arm with tape and an arm board, preventing flexion at the elbow. The brachial artery lies lateral to the medial epicondyle but medial to the biceps tendon, and courses through the antecubital fossa. Palpate and stabilize the artery using sterile technique. Direct the needle tip and catheter slowly along the axis of the artery, aimed toward the arterial pulsation, at a 20- to 30- degree angle to the distal skin (Fig. 208-12).
- 8. Puncture is detected when blood appears in the needle hub. For radial, dorsalis pedis, and brachial artery cannulation, while holding the needle fixed, advance the catheter-over-needle into the artery (Fig. 208-13). For femoral artery cannulation, do the same unless the Seldinger technique is desired. With the Seldinger technique, insert the wire through the needle into the artery, remove the needle, insert the catheter over the wire, and

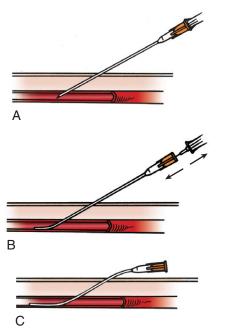

**Figure 208-12 Brachial artery cannulation**. (Modified from American Heart Association: Textbook of Advanced Cardiac Life Support. Dallas, American Heart Association, 1997.)

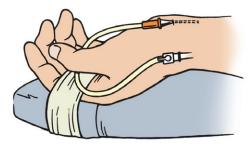

remove the wire. A modified Seldinger technique can be used for radial artery cannulation. Although the Seldinger technique is useful, an ordinary cannula is usually quicker and easier.

**NOTE:** The wire-guided technique may be more successful for arterial cannulation when the pulse is either weak or absent, especially in female patients.

- 9. If the artery cannot be cannulated after the flash of blood has appeared, the posterior artery wall has probably been penetrated. Remove the needle entirely, slowly withdraw the catheter until blood flows into it, and readvance the catheter.
- For the Seldinger technique, to minimize the chance of intramural insertion or dissection, make sure the wire passes without any resistance.

**Figure 208-13 A–C,** Technique for radial, dorsalis pedis, or brachial artery cannulation. Insert the angiocatheter through the skin and cannulate the artery.

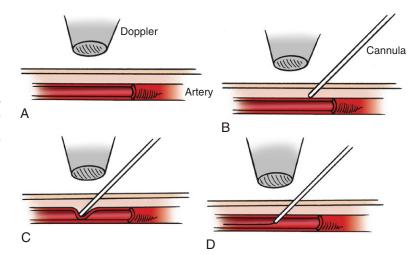

**Figure 208-14** Attach connector tubing to the catheter and fix in position.

- 11. If after three attempts the artery has not been entered, discontinue the procedure on that side and attempt on the other side or at another site. Pressure should be applied to the unsuccessful site for at least 10 minutes, followed by a pressure dressing. A cutdown might also be considered, with the technique described in a later section being similar to that used for venous cutdown (see Chapter 209, Venous Cutdown).
- 12. After insertion, advance the catheter until the hub is in contact with the skin and attach it to the connector tubing (Fig. 208-14). Flush the catheter and zero the transducer system by opening the three-way stopcock to atmosphere and pushing the "zero" button on the pressure monitor. Return the three-way stopcock to the patient position and observe the arterial tracing. It should be sharp and clean. If it is not, reposition the catheter. If successful, stitch the catheter into position, apply antibiotic ointment, and cover with a sterile dressing. For radial or brachial artery cannulation, remove the 3-inch roll.
- 13. Staff should check the extremity every 4 hours for perfusion, and the site for signs of a hematoma or early cellulitis. The dressing should be changed daily along with regular flushing of the line as long as it remains cannulated. After catheter removal, observe the patient for bleeding, extremity pain, numbness, swelling, or discoloration.

**NOTE:** If the Seldinger technique is not used, the "liquid stylet" method may be useful. If a flash of blood is seen in the hub and the artery cannot be cannulated, fill a 10-mL syringe with 5 mL of sterile normal saline. Attach the syringe to the catheter hub and aspirate 1 to 2 mL of blood to verify intraluminal position. The blood should be very easy to aspirate. Slowly inject fluid from the syringe and advance the catheter behind the fluid wave.

## Alternative Method for Artery Cannulation: Doppler Ultrasonography Guided

- 1. Position the extremity in the position previously described and prepare, anesthetize, and drape the area.
- 2. Using antiseptic ointment (e.g., povidone—iodine) as transmission gel, have an assistant align the hand-held Doppler with the artery, at a site slightly proximal to the puncture site. The assistant should pass it back and forth medial to lateral over the artery and determine the point of maximal flow. He or she should then hold the Doppler in place at the point of maximal volume.
- 3. Insert and advance the catheter-over-needle slowly and with constant pressure, at a 45-degree angle to the skin and directed toward the point of maximal flow (Fig. 208-15A and B).
- 4. Contact with the artery is discerned by a slight decrease in arterial flow sound.
- As the needle compresses the artery before puncture, the flow sound may transiently decrease or cease (Fig. 208-15C and D).
- The characteristic sound of arterial blood flow should resume as the artery is punctured and a flash of bright red blood is seen in the needle hub.

**Figure 208-15** Radial artery cannulation guided by Doppler ultrasonography. **A** and **B**, Doppler locates the artery and helps in guiding the cannula. **C** and **D**, The catheter occludes the artery temporarily and then punctures the arterial wall (blood flashes in catheter), after which it is placed intraluminally.

Advance the cannula, and secure and calibrate it as described previously.

## Alternative Method for Radial or Brachial Artery Cannulation: Cutdown

- Position the wrist or arm in the previously described position and prepare, anesthetize, and drape the area.
- 2. Wearing sterile gloves and maintaining sterile technique, make a 1.5- to 2-cm transverse skin incision, perpendicular to the artery yet centered over it. Limit the depth of the incision to the skin; avoid cutting into the subcutaneous tissue to avoid damaging the nerve, artery, vein, lymphatics, tendons, or other nearby or deeper structures.
- 3. Using a mosquito hemostat, spread the subcutaneous tissue in a direction perpendicular to the incision, but along and above the artery. Expose approximately a 1-cm length of the artery.
- 4. Pass a nylon suture under the artery (internal suture), and prepare to elevate the artery to assist with cannulation.
- Insert a catheter-over-needle through the skin, distal to the incision, and tunnel it under the skin and into the visible area of the incision.
- 6. While the clinician directly observes and controls the artery with two fingers of his or her nondominant hand or the suture, advance the catheter-over-needle into the artery. For the clinician to avoid being sprayed with arterial blood, the suture can be tied (lightly, without cutting the suture) proximal to where the catheter-over-needle will be inserted into the artery. After puncturing the artery with the catheter-over-needle, the knot in the suture can then be loosened (or released), as needed, to advance the catheter-over-needle further into the artery.
- 7. Advance the cannula, release the internal suture completely, and externally secure the arterial line and calibrate it as described previously. After the arterial line is secured externally and calibration confirmed, suture will also be needed to close the incision.

**NOTE:** Unlike venous cutdown (a procedure in which the internal suture is often tied, cut, and left within the incision), when an arterial cutdown is performed for arterial line insertion, the internal suture is only used temporarily to provide control while the artery is being cannulated.

## Troubleshooting for a Variance between Cuff and Intra-arterial Pressure and Preventive Maintenance for Accurate Readings

A variance or disparity of 5 to 20 mm Hg between measured cuff (indirect) and intra-arterial (direct) pressures is normal and expected. If the intra-arterial pressure is higher than cuff pressure,

possible causes include improper cuff size or placement and improper calibration or zeroing of the transducer.

If cuff pressure is recorded as higher than intra-arterial pressure, either improper cuff size, equipment malfunction, or technical error is likely. Damping of the arterial waveform suggests a problem with the intra-arterial measurement. Air bubbles or blood in the line or transducer dome, a clot at the catheter tip, mechanical occlusion of the catheter or tubing, and loose or open connections are all possibilities. If the arterial waveform is not dampened and the cuff size and placement are correct, other possible causes include failure to calibrate the sphygmomanometer or the transducer, or an error in electrically or mechanically zeroing the transducer.

The variance of 5 to 20 mm Hg may be physiologic because the arterial pulse wave is transformed as it travels peripherally. As a result, the systolic pressure may become higher and the diastolic pressure lower. MAP, however, is unchanged.

If the disparity is 20 to 30 mm Hg, severe vasoconstriction (e.g., patient with shock or hypothermia) may be the cause, and inevitably the auscultated cuff pressure is lower. With occlusive atherosclerotic peripheral disease, if the radial or dorsalis pedis artery has been cannulated, cuff pressures are frequently higher than the directly measured pressures because of the more distal location of cannulation.

If the disparity is greater than 30 mm Hg, the most common cause is resonance in the catheter system. This can be minimized by using stiff tubing that is kept as short as possible. Directly measured pressure may be significantly higher than cuff pressure when a single–end-hole catheter is used in a narrow artery with high flow. If the hole faces the flow, the direct blood pressure may be falsely elevated.

To minimize disparities and to maximize accurate readings, the following 10 preventive steps should be followed or considered:

- 1. Allow the transducer and the amplifier to warm up for at least 10 minutes before zeroing and calibrating the system.
- 2. Purge all air from the pressure system; always observe for bubbles in the line and attempt to remove them if seen.
- 3. Use stiff, noncompliant extension tubing of the shortest possible length. Avoid the use of more than one stopcock between the catheter and the transducer. Place the extension tube near the patient to prevent a pulsating line.
- 4. Electrically zero and calibrate the system with an accurate manometer or a water column.
- 5. Mechanically zero the transducer.
- At least once a shift, staff should check all fittings for tightness, check the zero setting (both electrically and mechanically), and check the calibration.
- Avoid draining blood samples from the full length of the plumbing system.

- 8. Maintain a continuous low-flow flushing system to avoid clotting.
- When the level of the patient is changed, recheck the mechanical and electrical zero positions and recalibrate the system if necessary.
- Avoid making adjustments to the amplifier except at the time of calibration.

#### **Complications**

- Significant blood loss can occur if the tubing becomes disconnected.
- Arterial thrombosis (risk minimized by reducing the duration of cannulation, by choosing larger arteries, and by flushing properly). The risk of thrombosis increases if the cannula is left in place for longer than 72 hours.
- Embolism, usually distal. Retrograde arterial embolism can also occur from retrograde flushing of the cannula, and may enter the cerebral circulation. This danger is greater with smaller patients. For all patients (and especially for smaller patients), make sure to either maintain a slow continuous flushing system or to use volumes of heparinized solution smaller than 3 mL to avoid dislodging thrombi.
- Arterial occlusion. With the Seldinger technique, it is possible to
  cause a small dissection and arterial occlusion by passing the
  guidewire between the intima and the media. With any technique, the result can be stenosis or permanent occlusion.
- Ischemia or necrosis distal to the site of arterial thrombosis, embolism, stenosis, or occlusion.
- Hemorrhage or local hematoma.
- Aneurysm or pseudoaneurysm. The patient will present with a pulsatile mass. Management is surgical removal.
- Local infection or sepsis, particularly after about 4 days.
- Arteriovenous fistula. This is more common with femoral artery cannulation because of the proximity of the large vein.
- Neurologic complications, same as with arterial puncture.
- Vasovagal reactions.

**NOTE:** A vascular surgeon should be consulted immediately if arterial flow is compromised in any way.

#### **Postprocedure Patient Education**

Explain to the alert patient and family the greater danger of a disconnected arterial line compared with a normal IV line. Instruct the patient not to rub or manipulate the site, line, or connectors. The patient should report any local pain, swelling, discoloration, or numbness at the site, or any bubbles in the line. He or she should also report any blood or dampness near the site. After catheter removal, the patient should report any bleeding, extremity pain, numbness, swelling, or discoloration.

#### **CPT/BILLING CODES**

#### **Arterial Puncture**

36600 Arterial puncture; withdrawal of blood for diagnosis

#### **Percutaneous Arterial Line Placement**

- 36620 Arterial catheterization or cannulation for sampling, monitoring, or transfusion (separate procedure); percutaneous
- 36625 Arterial cutdown

#### **ICD-9-CM DIAGNOSTIC CODES**

#### **Arterial Puncture**

- 250.1 Diabetic ketoacidosis, without mention of coma
- 276.2 Acidosis, lactic, metabolic or respiratory
- 276.3 Alkalosis, metabolic or respiratory
- 276.4 Acid-base mixed disorder
- 415.1 Pulmonary embolism and infarction
- 427.5 Cardiac or cardiorespiratory arrest
- 428.1 Left heart failure, with pulmonary edema or cardiac dyspnea (cardiac asthma)
- 491.20 Chronic obstructive bronchitis, with emphysema, without exacerbation
- 491.21 Chronic obstructive bronchitis (COPD), with acute exacerbation
- 492.8 Emphysema, NOS
- 493.00 Asthma, extrinsic, unspecified
- 493.01 Asthma, extrinsic with status asthmaticus
- 493.02 Asthma, extrinsic, with acute exacerbation
- 518.5 Pulmonary insufficiency following shock, trauma, or surgery
- 518.81 Respiratory failure, acute, NOS
- 518.82 Respiratory distress or other pulmonary insufficiency, acute, not elsewhere classified
- 518.83 Respiratory failure, chronic
- 518.84 Respiratory failure, acute and chronic
- 780.01 Coma
- 785.50 Shock, unspecified, without mention of trauma
- 785.51 Shock, cardiogenic
- 785.52 Shock, septic
- 785.59 Shock, other (hypovolemic, septic)
- 786.05 Shortness of breath
- 786.09 Respiratory distress or insufficiency, NOS
- 799.01 Asphyxia
- 799.02 Hypoxia
- 799.1 Respiratory arrest
- 986 Carbon monoxide, toxic effect

#### **Percutaneous Arterial Line Placement**

In addition to ICD-9-CM diagnostic codes used for arterial puncture, the following are commonly used for arterial lines:

- V42 Organ or tissue replaced by transplant
- V43 Organ or tissue replaced by other means
- V45 Postprocedure states
- V45.81 Postprocedure status, aortocoronary bypass
- V46.1 Dependence on machines, respirator (ventilator)
- 401.0 Hypertension, accelerated, malignant
- 410.9 Myocardial infarction, acute, NOS or unspecified site
- 411.1 Angina, unstable
- 434.9 Cerebral artery occlusion, unspecified

## Venous Cutdown

Wm. MacMillan Rodney • J.R. MacMillan Rodney

Obtaining vascular access is a life-saving procedure for critically ill patients in a variety of situations, but hypovolemic shock and cardiac arrest are the most common vascular access emergencies. Venous cutdowns were first described in World War II. With the advent of intensive care units in the 1960s, surgical cutdowns were frequently replaced by percutaneous approaches to the subclavian and internal jugular veins. In the 1970s, placement of these "central lines" became core curriculum in the newly established course known as Advanced Cardiac Life Support (ACLS). This course was usually taught by demonstration and did not require the traditional surgical skills of dissection and suture.

By 1980, the American College of Surgeons implemented the Advanced Trauma Life Support (ATLS) course, which required live tissue for the demonstration of vascular access techniques. These were "venous cutdowns," but percutaneous techniques have replaced most of the cutdowns. Plastic simulators do not realistically reproduce the in vivo experience. More recently, ultrasonography has dramatically improved the ability to visualize central and peripheral veins, often directing cannulation.

In situations where ongoing chest compressions, burns, or trauma make central line placement difficult, the intraosseous route (see Chapter 198, Intraosseous Vascular Access) is quickest and most reliable for clinicians with limited surgical experience. However, intraosseous needles and central line kits are not as universally available as scalpels, hemostats, and suture. In developing countries and most locations more than 1 mile from an academic medical center, venous cutdown is the most readily available method for rapid vascular access. Ironically, clinicians in these locations are often less likely to have any experience or training with venous cutdown.

This chapter describes cutdowns of the distal great saphenous vein near the ankle and the proximal great saphenous vein beneath the inguinal crease. Brachial or basilic vein cutdowns in the antecubital fossa are rarely a first choice because of the time required for dissection, but are also discussed. In cases where the patient is undergoing chest compressions, space around the patient can be limited, and choosing a more distal location is usually better.

#### **INDICATIONS**

- Multiple failed attempts at percutaneous insertion in a critically ill or injured patient
- Hypotensive shock
- Patient requiring immediate administration of intravenous (IV) fluids or drugs
- Cardiac or respiratory arrest
- Burns, trauma, or ongoing resuscitation preventing timely insertion of percutaneous central lines
- Intraosseous access contraindicated (see Chapter 198, Intraosseous Vascular Access) or equipment not available
- Surgical consultation not available (e.g., because of time or distance limitation)
- Lack of percutaneously accessible vein (e.g., obesity, unusually small or fragile veins [as in some adults and most infants], or

venous sclerosis from aging, IV drug abuse, or previous multiple venipunctures)

#### **CONTRAINDICATIONS**

- When less invasive and adequate alternatives (e.g., intraosseous, percutaneous central or peripheral lines) are immediately available
- Long bone fracture present proximally in extremity
- Evidence of severe peripheral vascular disease such as thrombophlebitis, vascular insufficiency, history of vein stripping, history of vein sclerosis (clinician should consider different site)
- Lack of equipment
- Local infection, burns, or trauma in the area of the cutdown (relative)
- Prolonged use for administration of hypertonic fluids (*relative*)
- Inadequate local arterial supply (relative, arterial supply is important for postprocedural healing, so consider a different site)
- Bleeding disorder (relative)

#### **EQUIPMENT**

- Tourniquet and tape
- Sterile gloves, goggles, equipment to follow universal blood and body fluid precautions
- Sterile gauze sponges, gauze pads, and drapes
- Antiseptic skin preparation (if time permits), such as povidoneiodine or chlorhexidine soap or solution (alcohol is not preferred)
- A 3- to 5-mL syringe of local anesthetic (any kind of lidocaine; epinephrine is not necessary but is not harmful)
- Basic surgical equipment (e.g., scalpel [no. 10 or no. 15 blade for skin, no. 11 blade for minivenotomy), hemostats [large and mosquito, curved and straight], thumb forceps [pickups] with and without teeth, suture scissors, tissue dissection scissors [Metzenbaum], and a needle holder)
- Although silk ligatures (4-0) for the vein and nonabsorbable skin suture (4-0) have been recommended for the skin, this is an emergency and any suture will work. Generally, braided or monofilament absorbable sutures varying from 0 to 4-0 work fine. Concerns about infection risk with braided suture are more theoretical than real. Silk is the most reactive of all sutures in the skin and is not the first choice.
- IV fluids and setup. Cannulation is possible using a wide variety
  of tubes and catheters. Using the IV tubing itself (hub cut off) to
  cannulate permits the most rapid infusion but usually requires the
  proximal saphenous, and a backup IV catheter should be available. Ten- to 14-gauge plain peripheral IV catheters are almost
  as good for infusion of large amounts of fluid, but anything will
  work if cardioactive drugs are needed.
- High-frequency ultrasonography (5 to 10 MHz) and ultrasound gel to visualize or define the venous anatomy at the groin or antecubital fossa (optional; if time and the urgency of the situation allow)

## PATIENT PREPARATION AND GENERAL CONSIDERATIONS: ANATOMY

- 1. The clinician should be familiar with the basic anatomy of the area (Fig. 209-1).
- If the patient is alert, explain the need for IV access and the procedure. If time and the urgency of the situation allow, obtain informed consent.
- 3. For distal saphenous or basilic vein cutdowns, have an assistant apply a tourniquet proximal to the incision site and control it. This will enable the clinician to more easily visualize and palpate the vein. A tourniquet applied high on the thigh may help with locating the proximal saphenous vein. To minimize bleeding, tourniquets should be released at the time of venipuncture. Observe universal blood and body fluid precautions.
- 4. Cleanse the skin in the area around the vein and incision site thoroughly with antiseptic soap or solution.
- 5. To provide ample working space, if time and the urgency of the situation allow, extend a wide sterile field 8 to 10 cm proximally and distally and apply sterile drapes.
- 6. Regardless of which cutdown site is chosen, incisions can be made horizontally (i.e., laterally), which is also transversely. When subcutaneous fat protrudes from the incision, use blunt dissection and spread the tissue longitudinally along the axis of the vein. All of these veins are in superficial fat layers, so with a proximal saphenous or basilic vein cutdown, if the incision exposes muscle fascia, it is too deep.
- 7. The vein should appear pulseless and thin-walled, and it should blanch with the application of distal traction. If a vein is not readily identified, have an assistant tighten the tourniquet, which may make it more apparent or palpable.
- 8. With all cutdowns, the vein should be dissected free and isolated for 2 to 4 cm along its axis.

#### **CUTDOWN**

#### **Distal Saphenous Vein (Ankle)**

#### **Advantages**

- No interference or disruption of other resuscitative procedures (e.g., obtaining blood gases in same area, cardiopulmonary resuscitation [CPR], or endotracheal intubation)
- IV access on inferior side of diaphragm
- Minimal training needed and low risk of complications compared with central access
- No valves at this level of the vein because of the minimal volume and pressure
- Most consistent vein of the lower extremity, especially in its location anterior to the medial malleolus

#### Disadvantages

- Phlebitis and infection are common complications of the lower extremity cutdown
- Less than ideal route for cardiac drug administration (especially during CPR)
- Not good for hypertonic solutions (risk of sclerosis)
- May be absent if the patient has had vein stripping or harvest (e.g., used for a coronary artery bypass graft) or nonfunctional due to prior cutdown
- Older patients may have vein narrowing
- May not be useful in the patient with unstable pelvic fracture or major knee trauma because of iliofemoral venous interruption

#### Technique

1. With the tourniquet in place, palpate the distal saphenous vein just anterior to the medial malleolus (see Fig. 209-1B).

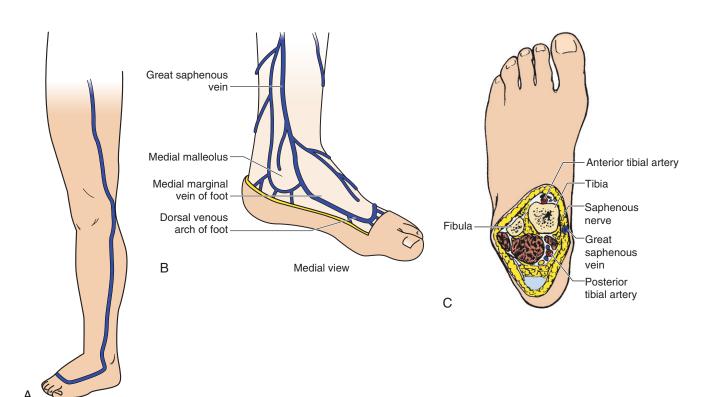

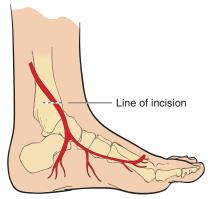

Figure 209-1 A, Anatomy of great saphenous vein of the lower extremity. B, Superficial veins of the leg and foot (great saphenous vein at the ankle). C, Cross-sectional view; the great saphenous vein may be isolated easily and safely at the ankle. Only the minor saphenous nerve lies nearby.

**Figure 209-2** Anatomic relationship of the saphenous vein and the line of incision.

- 2. Incise skin above the medial malleolus starting at the proximal anterior border of the tibia and extending to the posterior border of the tibia (Fig. 209-2).
- 3. Using a closed, curved hemostat, with the point downward and adjacent to the tibia, advance the instrument in the line of the incision to lift the superficial tissue (Fig. 209-3).
- 4. Rotate the point upward, still holding the tissue. Spread to reveal the distal saphenous vein and nerve.
- 5. Proceed to cannulation as described in that section.
- 6. Apply dressing (Fig. 209-4).

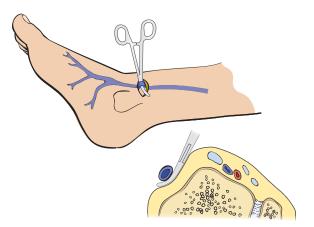

#### **Proximal Saphenous Vein (Groin)**

#### **Advantages**

- IV access on inferior side of the diaphragm
- Minimal training and risk compared with central access
- Larger vein caliber facilitates cannulation and bolus infusion in profoundly hypovolemic patients

#### Disadvantages

- Phlebitis and infection are common complications in the groin
- Less than ideal route for cardiac drug administration (especially during CPR)
- Not good for hypertonic solutions (risk of sclerosis)
- Proximity of femoral neurovascular bundle and other structures may introduce greater risk for complications

**Figure 209-3** Curved mosquito clamp is inserted into the edge of the incision and the tip turned downward and placed adjacent to the tibia. It is then advanced under the saphenous vein and swept across the tibia. Then the clamp is turned over so that the tips are pointed upward. The tips are spread to reveal the saphenous vein and nerve.

Figure 209-4 Dressing to prevent decannulation.

 May not be useful in patient with unstable pelvic fracture or major knee trauma because of iliofemoral venous interruption

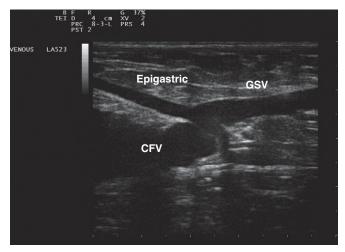

#### Technique

- 1. If time and the urgency of the situation allow, identifying and visualizing the anatomy with a high-frequency (5 to 10 MHz) ultrasonography transducer is very helpful (Fig. 209-5). (Also see Chapter 225, Emergency Department, Hospitalist, and Office Ultrasonography [Clinical Ultrasonography].) The high-frequency probe (even the transvaginal probe is a high-frequency probe) can be applied directly to ultrasound jelly on the skin to obtain images.
- Incise laterally starting at the junction of the scrotal/labial fold and the medial thigh (Fig. 209-6). Extend the incision to the outer portion of the mons pubis. Visible muscle fascia means the incision is too deep.
- The proximal saphenous vein lies in the superficial fat layer where a vertical, imaginary line starting from the pubic tubercle crosses the incision (see Fig. 209-6). Cannulate as noted in that section.

#### **Basilic Vein (Antecubital Fossa)**

#### **Advantages**

- IV access on superior side of the diaphragm
- Minimal training and risk compared with central access
- Larger vein caliber facilitates cannulation and bolus infusion in profoundly hypovolemic patients

**Figure 209-5** High-frequency (5 to 10 MHz) ultrasonogram of the groin, defining bifurcation of great saphenous vein (GSV) from common femoral vein (CFV).

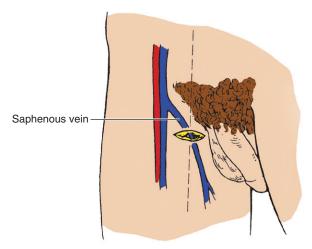

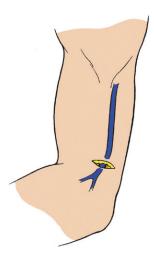

Figure 209-6 Cutdown location for great saphenous vein at the groin.

#### Disadvantages

- With ongoing CPR, percutaneous cannulation can be difficult at this site.
- Compared to the groin, the smaller diameter of the basilic vein theoretically limits rapid infusions of large volume. However, the cannulas are the same size in all sites; therefore, the basilica vein diameter is unlikely to be a negative factor.
- Deep dissection in the antecubital fossa can damage other structures.

#### Technique

- Take the distance between the olecranon and the acromion and divide it into thirds. With the tourniquet applied proximally, palpate the vein on the medial aspect of the arm where it lies in the groove between the triceps and biceps muscles. On the medial arm, the vein follows a course slightly anterior and superficial to the brachial artery.
- 2. Make a horizontal, superficial incision from the biceps across the groove to the triceps (Fig. 209-7).
- Locate the basilic vein by dissecting the superficial fat layer. Visible muscle fascia or the brachial artery means the incision is too deep.
- 4. If time and the urgency of the situation allow it, identifying and visualizing the anatomy with a high-frequency (10 MHz) ultrasonography transducer is very helpful (see Fig. 209-5; also see

**Figure 209-7** Incision is made between the biceps and triceps for basilic vein cutdown (right arm).

Chapter 225, Emergency Department, Hospitalist, and Office Ultrasonography [Clinical Ultrasonography]). The basilic vein will best be visualized with the tourniquet in place.

5. Proceed to cannulation.

#### **CANNULATION**

- 1. Isolate 3 to 4 cm of the chosen vein, dissecting aside loose adipose or adventitial tissue. The scissors can be spread longitudinally along the length of the vein to improve access and help visualize it.
- 2. Pass suture ties under the vein, both proximally and distally. Pass the distal suture as far distal as possible; use this as a retractor to bring the vein into the incision.
- 3. If the distal vein is to be sacrificed, the distal ligature should be tied and left long to help control and manipulate the vein. Clamp the ends of the ligature with a hemostat and use its weight to maintain tension on the ligature.
- Place traction on the proximal suture to minimize rebleeding; it should not be tied at this point.
- 5. Loosen the tourniquet if one has been applied.
- 6. Select a site near the distal ligature for venotomy. If the vein is large enough, it can be catheterized directly. Otherwise, incise one third of the vein's diameter at a 45-degree angle to the skin in distal-to-proximal fashion (Fig. 209-8A). The result should be a V-shaped incision (Fig. 209-8B). While maintaining proximal ligature traction, expand the lumen with a mosquito hemostat (Fig. 209-8C).

**EDITOR'S NOTE:** Avoid cutting the entire vein with the scissors or scalpel because it may result in retraction of the vein from the incision, thereby increasing the difficulty of the procedure.

- 7. Once the skin has been entered through a *separate* stab wound, introduce the cannula through the vein incision, maintaining the same 45-degree angle (Fig. 209-9). This is the most difficult portion of the procedure. Use caution in great saphenous vein cannulations, making sure not to occlude the femoral vein with the cannula (avoid advancing the cannula too far).
- Aspirate air from the cannula; tie the proximal ligature around the cannula and vein wall.
- 9. Cut both ligatures and close the wound (Fig. 209-10).
- Remove the tourniquet and observe for incision leakage of blood or fluid.
- 11. Secure the catheter hub to the skin with an additional stitch. Apply sterile dressing.

## MINICUTDOWN WITH ANGIOCATHETER OR SELDINGER WIRE

The minicutdown is the fastest technique when an angiocatheter needle (standard catheter-over-needle) of adequate size (16 to 18 gauge) or a Seldinger wire introducer or modified Seldinger wire kit is available. The vein is located and isolated surgically as previously described, but the incision can be much smaller ("mini," or just large enough to locate the vein). Then, the angiocatheter unit is placed through the skin approximately 1 cm distal to the incision. The angiocatheter is threaded into the vein in the same manner as with percutaneous catheterization. An optional suture through the skin proximal to the incision, around the catheter and vein, and then tied loosely can stabilize the catheter in the vein. However, inserting the angiocatheter through skin distally usually stabilizes it. Closure of the wound provides further stabilization. The hub should also be stabilized with an additional skin suture. In 1 to 2 days, after the patient is stable and has routine peripheral IV access, the hub (and optional catheter) sutures can be removed and the Teflon catheter withdrawn without reopening the incision.

To ease cannulation of the vein, a straight hemostat can be inserted beneath the vein and spread open. The scalpel can then be

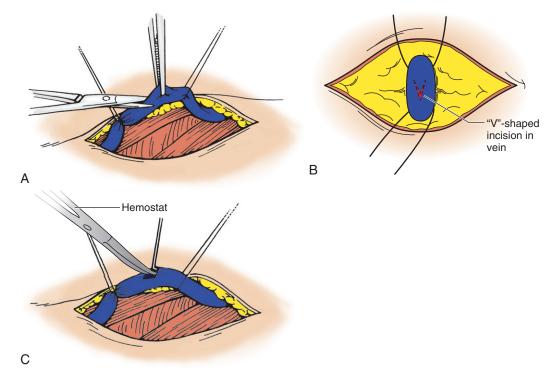

Figure 209-8 A, Angled wedge cut is made in the anterior wall of the vein. Traction should be maintained on the vein with proximal and distal ligatures. If sacrificed, the distal vein ligature can be tied. B, A V-shaped incision is made in vein. C, The vein is dilated with a hemostat.

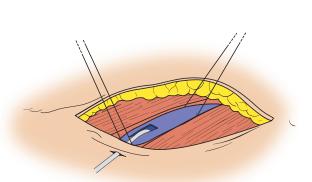

used to make a 1- to 2-mm venotomy (Fig. 209-11) and the angio-catheter inserted through the venotomy.

The Seldinger technique for venous cutdown can also use a small, 1- to 2-mm, venotomy (see Fig. 209-11) and a Seldinger wireguided catheter (found in prepackaged central line set). The Seldinger unit comes assembled with dilator and catheter. The catheter-over-needle is advanced though the skin 1 cm distal to the incision and then through the venotomy. The needle is removed and the wire advanced into the vein. The catheter is then removed while the guidewire stays in place. Next, place the dilator through the introducer sheath and thread the combined dilator—introducer sheath down the guidewire. Holding the free end of the guidewire to prevent it from advancing, and using a twisting motion, advance the dilator and introducer sheath further down the guidewire and into the venotomy. This effort also dilates the vein. Most of the time, this technique eliminates the need for tying off the distal vein.

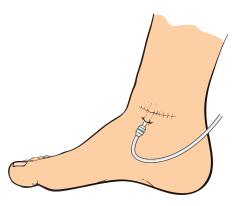

When the hub of the introducer sheath reaches the skin level, remove the guidewire and dilator as a unit, leaving the introducer sheath in place. Securing the introducer in the vein with a suture around them both is usually not necessary.

The modified Seldinger wire-guided technique for venous cutdown is even easier to learn and has been shown to be 22% faster than the classic technique. Assemble the unit (Fig. 209-12) by placing the dilator through the sheath and then inserting the guidewire through the dilator. The guidewire should protrude 3 to 4 mm beyond the tip of the dilator. This guidewire is then inserted through a 1- to 2-mm venotomy and advanced. With a twisting motion, the entire unit is then inserted over the guidewire, up to the hub.

The skin incision can then be closed with sutures and the catheter hub sutured in place. Even when pressure infusion techniques are used, additional sutures may not be necessary.

**Figure 209-9** Catheter is threaded through a separate skin stab wound and then into vein.

**Figure 209-10** Incision is closed to minimize risk of infection and catheter is then sutured in place.

**Figure 209-11** A spread straight hemostat and no. I1 blade used to make 2-mm minivenotomy incision. (From Klofas E: A quicker saphenous vein cutdown and a better way to teach it. | Trauma 43:985–987, 1997.)

#### **COMPLICATIONS**

Possible complications include hematoma, embolism, bacteremia, and sepsis. These are rare. There is always the possibility of injury to nearby structures, especially using the basilic vein technique, which is the most difficult approach. The second most difficult approach uses the proximal saphenous vein. The distal saphenous vein is least likely to result in damage to other structures. In the unstable emergency patient, there is the possibility of taking too much time during an attempt to perform venous cutdown, leading to a worsening of the clinical situation.

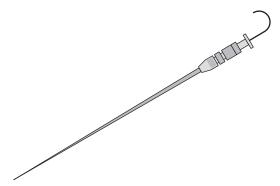

Figure 209-12 The wire-guided catheter, already mounted on the wire and dilator. (From Klofas E: A quicker saphenous vein cutdown and a better way to teach it. | Trauma 43:985–987, 1997.)

#### **CPT/BILLING CODES**

- 36410 Venipuncture, child over 3 years or adult, necessitating physician's skill for diagnostic or therapeutic purposes (not to be used for routine venipuncture)
- 36425 Venipuncture, cutdown; aged 1 year or older
- 76937 Ultrasound guidance for vascular access

#### **ICD-9-CM DIAGNOSTIC CODES**

- 276.51 Volume depletion, dehydration
- 276.52 Volume depletion, hypovolemia
- 427.5 Cardiopulmonary arrest
- 459.0 Hemorrhage, nonspecific
- 459.89 Venofibrosis
- 772.9 Hemorrhage, unspecified in newborn (NOS)
- 785.50 Shock (without trauma), unspecified
- 785.52 Shock, septic or endotoxic
- 785.59 Hypovolemic shock (NEC)
- 799.1 Respiratory arrest
- 958.4 Hemorrhagic shock or shock syndrome due to trauma
- 995.0 Shock, anaphylactic

## **ELECTRICAL CARDIOVERSION**

Jeremy Fish

Transthoracic direct-current electrical shock, or electrical cardioversion, is a safe and effective procedure for terminating most sustained tachyarrhythmias. It is useful for converting acute arrhythmias that are causing clinical deterioration of the patient's condition, and for chronic arrhythmias that are symptomatic, carry a poor prognosis, or are unresponsive to drug therapy. Cardiac arrhythmias often can be converted to sinus rhythm with medications (chemical cardioversion), but electrical cardioversion refers to the direct application of electrical current.

#### **CARDIOVERSION VERSUS DEFIBRILLATION**

Cardioversion differs from defibrillation in that, with electrical cardioversion, the electrical discharge is synchronized with the R wave of ventricular depolarization to minimize the risk of triggering ventricular fibrillation. External paddles or patches are used to apply the electrical current, which causes total depolarization of the atria and ventricles. This depolarization frequently causes the instantaneous conversion of an arrhythmia to sinus rhythm.

Electrical defibrillation is a procedure in which nonsynchronized electrical current is applied to convert chaotic fibrillation, or pulseless ventricular tachycardia (VT), to a normal sinus rhythm. Defibrillation is warranted in an unconscious, pulseless, and apneic patient once ventricular fibrillation (VF) or pulseless VT is identified. Patients in VF or pulseless VT should receive immediate defibrillation at 360 joules (J) if using a monophasic device or 200 J if using a biphasic device. Defibrillation should be repeated at 360 J (monophasic energy) or 200 J (biphasic energy) if the rhythm does not convert. Defibrillation is an emergency procedure. One of the most generally accepted protocols for defibrillation is available through Advanced Cardiac Life Support (ACLS) courses given by many local hospitals and registered through the American Heart Association.

#### **INDICATIONS**

- Atrial fibrillation (AF)
- Atrial flutter
- Hemodynamically stable VT unresponsive to pharmacologic therapy
- Hemodynamically unstable VT with a pulse
- Hemodynamically unstable supraventricular tachycardic (SVT) arrhythmias
- Certain SVT arrhythmias unresponsive to pharmacologic therapy, including bypass tract SVT (e.g., Wolff-Parkinson-White syndrome)

#### **CONTRAINDICATIONS**

#### **Absolute**

- Absent pulse (patient needs Basic Life Support measures or defibrillation)
- Severely unstable patient (patient needs resuscitation)

- Severe electrolyte disturbances
- Digitalis toxicity
- Left atrial or atrial appendage thrombus (for elective cardioversion)
- · Left ventricular mural thrombus

#### Relative

- Large left atrial diameter (>4.5 cm) in patients with AF
- Sick sinus syndrome
- Ectopic or multifocal atrial tachycardia
- Junctional or sinus tachycardia
- Minimal hemodynamic or clinical improvement while in sinus rhythm
- AF duration greater than 6 months
- Inadequate anticoagulation and more than 48 hours' duration of AF (unless transesophageal echocardiography [TEE] negative)

A left atrial diameter greater than 4.5 cm or AF duration greater than 6 months is associated with a low likelihood of maintaining sinus rhythm. Patients with sick sinus syndrome or sinoatrial node block should not undergo cardioversion until a pacemaker has been placed. Ectopic or multifocal atrial, junctional, and sinus tachycardias do not normally respond to cardioversion. These rhythms have an automatic focus arising from cells that are depolarizing at a rapid rate; delivery of a shock may actually increase the rate of the tachyarrhythmia. Patients with a history of minimal hemodynamic or symptomatic improvement while in sinus rhythm should not undergo cardioversion because of an increased risk-to-benefit ratio. Inadequately anticoagulated patients with AF of longer than 48 hours' duration have an increased risk of thromboembolic stroke or arterial embolization (5% rate in the first 2 weeks after cardioversion).

#### **EQUIPMENT**

- Hand-held paddle electrodes, or 8- to 12-cm diameter, selfadherent pad electrodes or posterior paddle adapter
- Electrode gel or patches
- ACLS equipment
  - Oxygen source, nasal cannula or face mask
  - Pulse oximeter
  - Airway and intubation equipment
  - Ambu bag
  - Suction equipment, tubing, and catheter
  - Emergency drug kit, including IV drugs and lines
  - Medications needed to follow ACLS protocols
- Electrocardiography (ECG) electrodes and ECG monitoring capabilities
- Blood pressure monitoring equipment
- Direct-current defibrillator-cardioversion unit, with synchronization capabilities and optional "quick-look" paddles
- Sedatives for procedural sedation for elective cardioversion (see Chapter 2, Procedural Sedation and Analgesia)

## Choice of Cardioversion Unit: Biphasic versus Monophasic

Biphasic waveform automated external defibrillators (AEDs) and cardioversion units were developed in the late 1990s and have been shown to provide superior atrial fibrillation conversion rates with lower-energy shocks compared with traditional monophasic units currently in use—86% of patients with AF returned to sinus rhythm after a single biphasic shock, versus 51% with the first monophasic shock. Most commercially available AEDs in the United States use biphasic waveforms, whereas most cardioversion units in hospitals and emergency departments continue to provide monophasic waveform shock. Cost and retraining of medical staff are likely barriers to wider use of biphasic cardioversion units.

#### **Electrical versus Chemical Cardioversion**

Given the procedural sedation (see Chapter 2, Procedural Sedation and Analgesia) required for nonemergent electrical cardioversion, much effort has been exerted to find an ideal antiarrhythmic medication for chemical cardioversion. The most effective agents, as recommended by the American College of Cardiology and American Heart Association (ACC/AHA), are the following:

- Ibutilide
- Dofetilide
- Propafenone
- Flecainide

Unfortunately, each of these agents has also been shown to be proarrhythmic—especially in the setting of decreased left ventricular ejection fraction (a relatively common finding in patients with AF). A less effective agent, amiodarone, has been shown to be safer in patients with a low ejection fraction, but it has delayed cardioversion effects in AF and is not currently approved for chemical cardioversion.

The advantage of chemical cardioversion is primarily related to the avoidance of procedural sedation in patients at high risk for airway compromise during procedural sedation (e.g., obstructive sleep apnea, known tracheal stenosis, prior tracheostomy, macroglossia). Like electrical cardioversion, chemical cardioversion in a nonurgent setting requires full anticoagulation for 3 weeks to avoid thromboembolic complications.

## Rhythm Control versus Rate Control in Persistent Atrial Fibrillation

Five recent studies have demonstrated little difference in clinical outcome between rate and rhythm control strategies for patients with AF. In fact, rate control strategy is associated with fewer hospitalizations and less adverse drug effects when compared with rhythm control. Based on this evidence, some authors now recommend rate control and anticoagulation as primary therapy for persistent AF. The American Academy of Family Physicians and the American College of Physicians Joint Commission on Atrial Fibrillation recommends rate control with chronic anticoagulation for most patients with AF (Snow and colleagues, 2003). Drugs recommended for rate control are metoprolol, atenolol, diltiazem, and verapamil, with digoxin being moved into second-line therapy. The Joint Commission further recommends that most patients converted to sinus rhythm from AF not be placed on rhythm maintenance medications because of the risks outweighing any potential benefits. For patients who are unable to take warfarin, aspirin 325 mg orally daily or clopidogrel 75 mg may be used. These drugs have the advantage of not requiring monitoring of the international normalized ratio (INR), although aspirin and clopidogrel are clearly inferior to warfarin for preventing cardioembolic events. The role of oral direct thrombin inhibitors in place of warfarin remains controversial.

#### PREPROCEDURE PATIENT PREPARATION

Urgent cardioversion is indicated when the patient is unstable. Examples include symptomatic hypotension with central nervous system changes or syncope resulting from decreased perfusion. If the patient is alert, briefly explain the procedure while connecting the equipment. Informed consent is unnecessary for a life-threatening situation. Document the indications and risks to the patient as time permits. The following preparation for elective cardioversion is not required for urgent cardioversion (i.e., if the clinical status of the patient is so tenuous that he or she would not survive).

#### **Echocardiography**

Transesophageal echocardiography is helpful before elective cardioversion to estimate left atrial diameter (see Chapter 90, Echocardiography). TEE can identify small atrial thrombi, especially in the left auricular appendage, that are not visible with transthoracic echocardiography in patients for whom anticoagulation with warfarin poses high risk.

#### Anticoagulation and Antiarrhythmics

All patients with AF for more than 48 hours should be anticoagulated adequately for 3 weeks before elective cardioversion because of the risk of embolizing intra-atrial thrombi when sinus rhythm (and atrial contractions) are reestablished. The incidence of emboli may be up to 5% for the first 2 weeks after cardioversion in nonanticoagulated patients. Recent trials indicate the benefits of anticoagulation in all patients with chronic AF. The INR for anticoagulation should be maintained between 2 and 3 for at least 3 weeks before and 4 weeks after the cardioversion. The routine use of anticoagulation in arrhythmias other than AF is controversial.

**EDITOR'S NOTE:** A TEE is much more sensitive than a transthoracic echocardiogram for detecting thrombi, especially in the atrial appendage. Although the absence of a detectable thrombus does not preclude thromboembolism after cardioversion, a TEE-guided strategy (Klein, 2000) for elective cardioversion of AF has resulted in outcomes comparable with those obtained using a conventional anticoagulation strategy.

There is some evidence suggesting that having the patient already on antiarrhythmic therapy before cardioversion may prevent recurrence. In the event the patient might chemically convert, he or she should have been adequately anticoagulated or have a TEE negative for thrombus before starting antiarrhythmics.

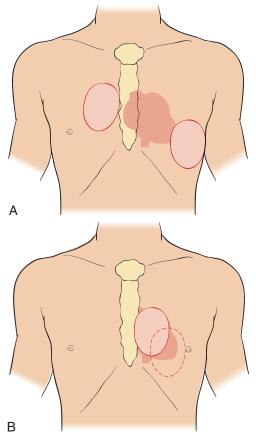

#### **Fasting and Informed Consent**

Instruct the patient to fast after midnight or for at least 4 to 6 hours before the procedure. Explain the indications for the procedure and the risk of complications. Explain that sedation will be used, but the patient may experience some achy discomfort in the arms and chest after the procedure. ECG monitoring for at least several hours will be necessary because of the risk of a recurrent or new arrhythmia. In addition, a minor skin irritation or burn may occur. Document the informed consent discussion and obtain the patient's signature on the consent form (see the sample patient consent form online at www.expertconsult.com).

## TECHNICAL CONSIDERATIONS FOR ELECTIVE CARDIOVERSION

#### **Paddle and Electrode Selection and Placement**

Apply the electrodes in either the standard paddle position (right upper parasternal [second or third interspace] and left apical [fourth

**Figure 210-1 A**, Standard electrode position. **B**, Alternative (anteroposterior) electrode position.

or fifth interspace, left mid-axillary line]; Fig. 210-1A) or the anteroposterior paddle position. For anteroposterior placement, the anterior electrode is centered over the sternum and the posterior electrode is placed between the scapulae, or both can be placed slightly to the patient's left, on the left side of the sternum and beneath the left scapula (Fig. 210-1B). Hand-held paddle electrodes or self-adherent pad electrodes 8 to 12 cm in diameter deliver adequate energy for cardioversion. To maximize the current flow to the heart, correct paddle or electrode placement is crucial. Either positioning technique is acceptable, but anteroposterior positioning may reduce energy requirements for cardioversion (through reduced electrical resistance) by up to 50%. In a large patient, this may increase cardioversion success. Anteroposterior placement is often used with disposable patches rather than paddles. Either paddles or electrodes must be positioned far enough apart so that electrical current travels through the heart. Gel or paste must be placed between the paddle or electrode and the chest wall to minimize resistance. However, avoid paste or gel smeared on the skin between electrodes, which might allow the current to travel along the external chest wall. Electrodes should also be placed far enough away from a pacemaker generator to prevent damage to its electrical components.

#### **Electrocardiographic Monitoring**

A set of ECG electrodes connected to the defibrillator should be placed on the patient so that the shock can be synchronized. An additional set of ECG electrodes can be connected to a telemetry monitor.

#### **Synchronization**

Synchronization refers to the delivery of electrical current to the myocardium during a nonrefractory period (e.g., not when repolarization of the entire myocardium is occurring). Shocking the myocardium during the relative refractory period (the T wave) can simulate the "R on T" phenomenon and induce VF. In synchronized mode, the energy is delivered at the peak of the QRS complex, the R wave. Synchronized administration reduces the energy requirements and complication rates of elective cardioversion.

Most defibrillators indicate when active synchronization is selected by highlighting the QRS peak (R wave). The practitioner can simply select and press the synchronization button for most cases of elective cardioversion. In cases with rapid ventricular response, the defibrillator in a synchronized mode may not be able to distinguish between the peak of the QRS complex and the peak of a T wave. As a safety feature, the defibrillator will not discharge if QRS complex and T waves cannot be distinguished. In this case, the provider should switch off the synchronization switch and perform unsynchronized defibrillation, realizing the increased risk of precipitating VT or VF. Alternatively, medications may be added to reduce the rapid ventricular response.

#### **Energy Selection**

Cardioversion is accomplished by passing an electrical current of sufficient magnitude through the heart to depolarize the myocardial tissues. Current flow is determined by the energy flow as measured in joules and by the resistance of the thoracic wall tissues as measured in ohms. The transthoracic resistance in an average adult is 70 to 80 ohms. If the transthoracic resistance is too high, the energy may fail to accomplish cardiac depolarization.

Some SVT arrhythmias are very sensitive to electrical current. Low energy settings may depolarize the myocardium in atrial flutter and allow the heart to resume a sinus rhythm. Recommended initial energy settings for cardioversion of various arrhythmias are listed in Table 210-1. For AF, the usual recommended initial energy setting is 100 J. However, recent evidence suggests that higher initial energy settings are more effective at achieving cardioversion, and some authors currently recommend an initial energy setting of 360 J.

Cardioversion energy for VT depends on the rate and morphologic features of the electrical activity. Monomorphic VT presents with a regular ECG form (wide-complex) and rate, and it is generally responsive to cardioversion beginning at energies of 100 J. Polymorphic VT has an irregular form and rate and is less responsive to electroshock therapy. Polymorphic VT behaves like VF, and the initial defibrillator shock energy should be 200 J (unsynchronized).

If the first shock fails to cardiovert any arrhythmia, repeated attempts should be undertaken with stepwise energy increases. The transthoracic resistance increases after each shock, so the energy must be increased to overcome that resistance. The standard sequence for synchronized cardioversion is 100, 200, 300, and 360 J; the energies used depend on the initial energy selected. For

TABLE 210-1 Recommended Initial Energy Settings for Electrical Cardioversion

	Initial Energy Settings (J)					
	Monophasic	Biphasic				
Atrial flutter Atrial fibrillation Paroxysmal supraventricular tachycardia Monomorphic ventricular tachycardia Polymorphic ventricular tachycardia	50 200 50 100 200	50* 100* 50* 50*				

<sup>\*</sup>Standards for biphasic cardioversion have not been established

example, after starting with 200 J, the second attempt to convert polymorphic VT should be with an energy of 300 J. Patients with large thoraces, chest wall deformities, or large amounts of adipose tissue may require higher initial settings.

Energy levels differ between monophasic and biphasic cardioversion units. In general, the energy requirements for biphasic cardioversion units are about half those for monophasic units. For example, patients with chronic AF often require 200 to 360 J of monophasic countershock; however, only 100 to 150 J of biphasic countershock is usually required (see Table 210-1).

#### **Environment and Personnel**

Elective cardioversion should be performed in a prepared environment, usually in a cardiac care unit with telemetry capabilities. The ACC/AHA guidelines (Tracy and colleagues, 2000) review the cognitive and technical skills necessary to perform external direct-current cardioversion and suggest a minimum requirement of eight prior supervised electrical cardioversions. Sedation or anesthesia is typically used with elective cardioversion, requiring appropriate personnel and monitoring.

#### **Choice of Sedation Agents**

Many factors play into the decision for procedural sedation during elective cardioversion, including anticipated energy levels for cardioversion, patient factors (e.g., airway, obesity, hepatic and renal disorders), and desired length of sedation. In general, the extent of sedation needed depends on the amount of energy to be used:

- 50 to 100 J: mild sedation
- Over 100 to 150 J: moderate to deep sedation

Mild sedation usually requires only short-acting benzodiazepines, such as midazolam or lorazepam, and fentanyl, a narcotic with less hemodynamic effects than morphine.

Moderate to deep sedation agents often used for cardioversion include the following:

- Etomidate: advantage, little hemodynamic compromise; caution in liver disease
- Propofol: advantage, rapid on, rapid off; caution, may cause hypotension
- Barbiturates, primarily thiopental: losing favor because of long recovery

See Chapter 2, Procedural Sedation and Analgesia.

#### **TECHNIQUE**

- Review laboratory values and echocardiography results or obtain an echocardiogram (see Chapter 90, Echocardiography). Confirm adequate anticoagulation and normal electrolyte (particularly potassium and magnesium) and serum digoxin (if indicated) levels. If indicated, patients should already be on a therapeutic regimen of antiarrhythmic medication. Review echocardiogram findings, noting the absence of intra-atrial thrombi (if appropriate) and an atrial diameter less than 4.5 cm.
- 2. Ensure that the patient has fasted.
- Obtain a resting 12-lead ECG and confirm the persistence of the rhythm disturbance.
- 4. Obtain informed consent (see the sample patient consent form, "Cardiac Procedure—Cardioversion," online at www. expertconsult.com).
- 5. Premedicate the patient with a sedative. Many experts recommend anesthesia standby if this service is available. Administration of a sedative (e.g., diazepam, midazolam) or a barbiturate can be combined with an analgesic (e.g., meperidine, fentanyl) to improve patient comfort.
- 6. The patient should be lying on a flat, dry surface.

- 7. Monitor the patient's ECG, pulse oximetry, and blood pressure throughout the procedure.
- 8. Initiate intravenous access. Apply supplemental oxygen.
- Have suction, resuscitation equipment, and support staff immediately available.
- 10. Apply conductive material and electrodes. (If gel is applied directly to the paddles, the paddles can be rubbed together to coat the electrode surfaces completely.)
- 11. Turn on the cardioversion unit.
- Select the appropriate energy level for the dysrhythmia, body habitus, and electrode positioning.
- 13. Turn on the synchronizer circuit. Look for markers on the R wave indicating synchronization mode. Adjust monitor gain, if necessary, until synchronization markers occur with each R wave.
- 14. Charge the capacitors to the preselected energy level.
- 15. Position the paddles or electrodes. Apply the pads firmly to the torso. (The paddles should be separated from each other by at least 2 to 3 cm to prevent arcing.)
- 16. Call "All clear!" to indicate all personnel should move away from the patient's bed to avoid receiving a shock. Double-check by visually confirming all personnel (including yourself) have moved back and have no physical contact with the patient or the bed.
- 17. Deliver electrical energy by depressing appropriate discharge buttons on both paddles. (There is often a brief delay. Keep buttons depressed until the shock is delivered.)
- 18. Assess the cardiac rhythm on the monitor.
- 19. Assess the patient and administer more sedation if needed.
- 20. If necessary, repeat cardioversion process (steps 12 through 17) at a higher energy setting.
- Remember to reset the synchronization switch, if necessary.
   Some defibrillators reset the switch to the "off" position after a shock is delivered.
- If cardioversion is unsuccessful after a shock at 360 J, abort the procedure and consider additional antiarrhythmic medications.

#### **COMPLICATIONS**

- Unsuccessful cardioversion
- Transient mild arrhythmias
- Conversion to VT or VF
- Bradvcardia, heart block
- Elevated cardiac enzymes (up to three times normal values)
- Localized cutaneous burns
- Accidental shock to attending personnel because of contact with the patient or bed
- Damage to electrical equipment in contact with the patient or bed
- Thromboembolic events
- Recurrence of original arrhythmia

If the original arrhythmia persists after more than three shocks and up to 360 J, the cardioversion is considered unsuccessful. In this case, the procedure should be aborted. Allow the patient to waken. Explain that the cardioversion was unsuccessful despite maximal safe efforts, and list the various options available to the patient and anyone else present. Options include internal cardioversion, antiarrhythmic medications, devices such as pacemakers, and no further treatment. Catheter ablation techniques are also sometimes available. In a significant number of patients with unresponsive AF, internal cardioversion with intracardiac electrode catheters has been successful. In this case, anticoagulation needs to be withheld temporarily because of the risk of bleeding at the catheter site. Alternatively, additional, more specific antiarrhythmic medications could be considered. The cardioversion may be reattempted after therapeutic blood levels are achieved (usually a few days). The

patient may decide that further attempts are not worth the perceived risks.

Other complications after cardioversion are uncommon in the absence of digitalis toxicity or hypokalemia and with a properly delivered shock. Bradycardia is sometimes noted immediately after cardioversion in patients with a history of inferior myocardial infarction. If the bradycardia is symptomatic, atropine may be used. Transient mild arrhythmias or creatine kinase elevations of less than three times normal may be noted, but they are generally inconsequential.

With any cardioversion, especially with rapid heart rates, there is a risk of producing a worse rhythm, such as VT or VF. Any attempted cardioversion that results in VF should be *defibrillated* (synchronization off) immediately, starting with 200 J of energy. On some defibrillators, the synchronization must be shut off manually to administer a nonsynchronized shock.

Application of adequate amounts of electrode paste to the paddles can minimize cutaneous burns. Electrical shock is a possibility for anyone in contact with the patient or the patient's bed. Any attached electrical equipment can be damaged. Systemic emboli may develop if the patient is not adequately anticoagulated, causing neurologic deficit or occlusion of a peripheral artery. The original arrhythmia may recur despite successful cardioversion.

#### POSTPROCEDURE MONITORING

Monitor the patient for 2 to 4 hours. An example of monitoring orders includes vital signs with neurologic checks every 15 minutes for 1 hour, then every hour for 2 hours. Provide continuous ECG telemetry during this time. Atrial or ventricular ectopy and bradycardia are not uncommon in the first 15 to 30 minutes after cardioversion.

## CENTRAL VENOUS CATHETER INSERTION

David James

Over the past several decades, the use of central venous catheters has increased to keep pace with other medical and technological advances. Emergency resuscitation protocols, specialized cardiovascular monitoring techniques, transvenous pacer insertion, and total parenteral nutrition protocols all demand access to a large central vein.

Expeditious placement of a large central venous catheter presents a challenge to the clinician, because the central veins are neither readily visible to the eye nor distinctly palpable. If the patient is critically ill or hypovolemic, the challenge is magnified. Fortunately, the larger central veins have predictable and constant relationships to readily identifiable anatomic landmarks.

In recent years, increasing emphasis has been placed on using ultrasound to guide placement of central venous catheters (see Chapter 225, Emergency Department, Hospitalist, and Office Ultrasonography [Clinical Ultrasonography]). Although ultrasonic guidance was not considered the standard of care in a recent informal survey of hospitalists, recent Medicare guidelines suggest monitoring very closely for iatrogenic puncture wounds of vital organs in hospitalized patients.

NOTE: Remember that a short, large-diameter IV catheter (e.g., 14-, 16-, or 18-gauge peripheral catheter) has less resistance to flow than a long, skinny central catheter! Rapid, large-volume infusion is faster with a peripheral, large-bore catheter and is preferred in an emergent situation. Depending on local availability and expertise, newer kits are available to rapidly and dependably obtain intraosseous vascular access (IOVA; see Chapter 198, Intraosseous Vascular Access). In some facilities, this has become the preferred temporary backup or alternative to obtaining central or peripheral venous access, especially in children (see Chapter 182, Pediatric Arterial Puncture and Venous Minicutdown).

#### **INDICATIONS**

- Venous access in those patients who are either so obese or so debilitated that their peripheral veins are not accessible for intravenous (IV) cannulation
- Emergency venous access after a cardiac arrest
- Administration of cardiac medications during cardiopulmonary resuscitation (CPR)
- Large-volume parenteral fluid administration when peripheral IV cannulation is not readily obtainable
- Central venous pressure monitoring
- Administration of certain chemotherapeutic agents
- Administration of vasopressor medications
- Administration of hyperosmolar or other irritating solutions (e.g., total parenteral nutrition) that have the potential to cause thrombophlebitis or to cause soft tissue necrosis if extravasation occurs

- Patients with significant burns on peripheral areas that may prevent placement of a peripheral catheter
- Placement of a pulmonary artery (Swan-Ganz) catheter (see Chapter 215, Swan Ganz [Pulmonary Artery] Catheterization)
- Placement of a temporary transvenous pacemaker wire (see Chapter 216, Temporary Pacing)
- Performance of right cardiac catheterization and pulmonary angiography
- Performance of hemodialysis or plasmapheresis

#### **CONTRAINDICATIONS**

#### **Absolute**

- Patient refusal
- Combative or agitated patient (may require procedural sedation, see Chapter 2, Procedural Sedation and Analgesia)
- Distortion of local anatomy or landmarks (e.g., prior surgery, trauma, radiation therapy, generalized obesity, orthopedic conditions, masses)
- Superior vena cava syndrome
- Bleeding diathesis or excessive anticoagulation and a noncompressible vessel
- Full-thickness burn or cellulitis over the proposed insertion site
- Pneumothorax or hemothorax on the contralateral side, or inability to tolerate a pneumothorax on the ipsilateral side (for subclavian and internal jugular locations)
- Prior injection of a sclerosing agent into the proposed vein
- Trauma to the proposed insertion site
- Venous thrombosis of the proposed vein
- Avoid internal jugular location if cervical spine fracture or penetrating neck injury
- Allergy to any component of the catheter such as latex
- Cardiac-paced patient (for Seldinger wire technique, whether pacer temporary, internal, or permanent)
- Highly unstable arrhythmias (for Seldinger wire technique, especially ventricular arrhythmias)
- · Right-sided endocarditis or mural thrombus

#### Relative

- Suspected injury to proposed vein (may then use vein on contralateral side, if no associated hemothorax or pneumothorax, when using subclavian or internal jugular)
- Morbid obesity
- Marked cachexia
- Vasculitis that predisposes to sclerosis or thrombosis of veins
- Previous long-term central catheterization or recently discontinued central catheter in proposed vein
- · Proposed mastectomy on same side of subclavian vein access

- Patients receiving ventilatory support with high end-expiratory pressures (if possible, for suclavian or internal jugular, ventilation should be briefly interrupted while central vein is cannulated with needle)
- Patients undergoing CPR (should use femoral or internal jugular vein locations)
- Children younger than 2 years old (for whom the internal jugular vein is preferred location)
- Severe hypovolemia (try large bore peripheral IV or IOVA first)
- Prosthetic right heart valve (Seldinger wire technique contraindicated)
- Avoid internal jugular or subclavian vein locations if patient unable to lie in the Trendelenburg position
- Left bundle branch block (use of Seldinger wire can cause complete heart block)
- Avoid internal jugular location if known severe carotid artery stenosis or atherosclerosis on the desired side (accidental artery puncture may result in plaque rupture and stroke)
- Personnel capable of handling complications not immediately available

#### **EQUIPMENT**

Many commercially prepared central venous catheter kits are available. Most institutions have a relationship with a hospital supplier that provides a catheter kit. These kits, often from a company such as Baxter or Cook, have all the components needed to insert a central venous catheter. These kits often utilize a Seldinger wire technique to place the catheter: a needle enters the vein, a guidewire is threaded through the needle into the vein lumen, and the cannulating needle is removed. A larger, flexible catheter is then passed over the guidewire into the vein, and the guidewire is removed.

- IV solution and connector tubing, flushed and ready
- Towel
- Pressure transducer and monitor, if monitoring central venous pressure
- Supplemental oxygen
- Continuous pulse oximetry and cardiac and blood pressure monitoring
- Fully stocked code cart and defibrillator nearby
- Surgeon's cap
- Sterile gloves and gown
- Sterile drapes
- Bio-occlusive dressing (e.g., Tegaderm, Opsite) to cover insertion site, especially useful if clear so the wound can be more easily inspected
- Goggles or eye protection

If a commercially prepared kit is unavailable, the following equipment list will supply what is needed:

- Sterile prep solution (chlorhexidine antisepsis preferred over povidone–iodine solution) and swabs
- Prep razor
- Sterile 4 × 4 inch gauze pads
- Lidocaine 1% to 2% with or without epinephrine for local anesthesia
- 3-mL syringe with 25-gauge needle for anesthetic injection
- 5-mL syringe with 22-gauge 1½- to 2½-inch seeker needle to find the vein
- 10-mL syringe with 2½-inch 18-gauge needle to introduce guidewire
- No. 11 scalpel blade and holder
- Guidewire or J-wire (flexible wire 45 cm long, 0.089 cm diameter, 3 mm radius of curvature)
- Central venous catheter
- 3-0 silk suture on straight needle to suture catheter into place

- Suture scissors
- Topical antimicrobial ointment
- Saline flushes

#### PREPROCEDURE PATIENT EDUCATION

If the clinical situation permits, informed consent must be obtained prior to the procedure. Inform the patient (or family) of potential major complications and their management, which could require chest tube insertion, surgery, or cardioversion. To minimize patient anxiety during procedure, explain the major steps of the procedure, the possible necessity of remaining in a head down (Trendelenburg) position during placement, and the near impossibility of a completely painless procedure.

#### **TECHNIQUES**

Several distinct approaches are discussed for placement of a central venous catheter. These approaches include cannulation of the subclavian vein (using both the supra- and infraclavicular routes), the internal jugular vein, and the femoral vein.

Generally, the preferred veins are on the *right* side of the patient. This preference is because the right-sided veins have a more direct course to the right atrium, and thus can be utilized for placement of a pacemaker wire or Swan-Ganz catheter with greater ease than the left-sided veins. The left-sided veins tend to have a more tortuous course and are in closer proximity to the thoracic duct and dome of the lung pleura.

The internal jugular vein is accessible without terminating CPR, although chest compressions and the lack of a carotid pulse may make access more difficult. However, having an internal jugular line requires limited patient neck mobility, which can be uncomfortable. so the subclavian route may be preferable for long-term lines. Likewise, a femoral line limits ambulation, so the subclavian route may be preferable. Ongoing or impending thrombolytic or fibrinolytic therapy is a contraindication to internal jugular puncture. Femoral vein access may be the easiest to obtain and may be preferable in emergencies or during CPR. It may also be preferred for patients with respiratory distress and pulmonary edema because the patient should not be placed in the Trendelenburg position. Supplemental oxygen should be provided and the patient monitored continuously during this procedure. Passage of a guidewire into the right side of the heart can induce arrhythmias and complete heart block; the clinician should be prepared to treat these problems accordingly.

#### Subclavian Venipuncture

The subclavian vein begins as a continuation of the axillary vein at the lateral border of the first rib, and it joins the internal jugular vein to form the innominate vein (Fig. 211-1). As it crosses behind the first rib, the subclavian vein lies posterior to the medial third of the clavicle. It is only in this "middle region" that an intimate relationship exists between the subclavian vein and the clavicle. The subclavian vein contains no valves and is between 1 and 2 cm in diameter for most people. The subclavian artery is superior and posterior to the vein, and is separated from the vein by the anterior scalene muscle. Other important structures nearby include the phrenic nerve; the thoracic duct (left side); lymphatic duct (on the right side, it joins the subclavian vein near its merger with the internal jugular vein); and the dome of the pleura of the lung. The dome of the pleura may extend above the first rib on the left side but is rarely found this far cephalad on the right.

#### **Patient Position**

Proper positioning of the patient increases chances of a successful cannulation and reduces risk of complications of this procedure. Place the patient in Trendelenburg position at an angle of 15 to 20

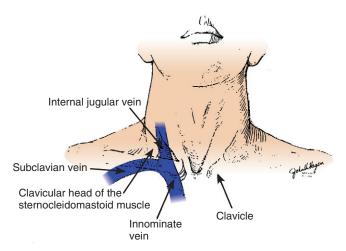

Figure 211-1 Relationship of great vessels in and about the right neck.

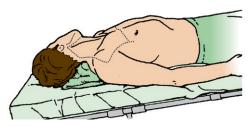

degrees (Fig. 211-2). This position fills these low-pressure great veins by gravity, thus making them swell in diameter and increasing your chances of finding them. It also reduces the risk of air embolism.

- Have the patient turn his or her head contralaterally. (Have an assistant turn the head if the patient is unable to do so.) This gives a wider field of operation.
- Consider placing a rolled-up towel vertically between the patient's shoulder blades. This may cause the shoulders to fall back from the clavicles, which could help to define the relevant anatomy and improve access the subclavian vein. However, it should be noted that certain experts avoid placing a towel between the shoulder blades because it can decrease the distance between the clavicle and first rib, thereby compressing the subclavian vein and making it more difficult to cannulate.

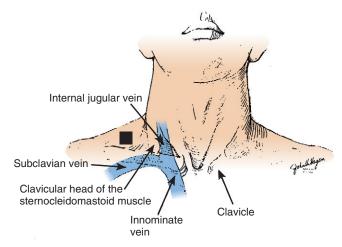

#### Supraclavicular Approach to the Subclavian Vein

This approach may sound complicated, but the author believes it to be the least complicated and most efficient technique. It is rapid, stays away from other vital structures, and is easily performed in patients undergoing CPR. Additionally, it is easily and reliably performed in an obese patient.

- 1. With the patient in the previously described position, locate the insertion area: a spot 1 cm lateral to the lateral head of the sternocleidomastoid muscle and 1 cm superior to the clavicular border (Fig. 211-3).
- 2. Review Figure 211-4 for an overview of the catheter-over-wire (Seldinger) technique described here.
- 3. Assemble equipment on a work surface of convenient height, and within your reach. Wash your hands and put on mask, cap, eye protection, sterile gown, and gloves. Strict sterile technique should be observed from this point onward. Cleanse the area with

**Figure 211-2** Moderate Trendelenburg position for subclavian central vein catheter insertion.

**Figure 211-3** Supraclavicular approach: *black box* represents entry point I cm lateral to the clavicular head of the *sternocleidomastoid* muscle, and I cm above the superior border of the clavicle.

skin prep solution (some kits will have a chlorhexidine or povidone—iodine prep swab enclosed), and drape to define a sterile field. Optimally, the entire neck and clavicular area are prepped. That way, in case of unsuccessful cannulation, another site can be attempted without having to repeat the prep. Drape as large of an area as possible, including the majority of the patient and the bed. A three-quarter sheet works well for this purpose. Follow universal blood and body fluid precautions.

- 4. Draw up 2 mL of 1% lidocaine into the 3-mL syringe, and raise a skin wheal at the site of the proposed insertion; infiltrate the deeper tissues with the remainder of the lidocaine.
- 5. With the 22-gauge needle on a 5-mL syringe, seek the subclavian vein; insert the needle at the entry point diagrammed in Figure 211-3. Aim just under the clavicle, angled toward the contralateral nipple. Usually, in people of normal weight and habitus, the vein is quite shallowly located. In an obese patient, or those with chest hyperinflation from chronic obstructive pulmonary disease, the vein is deeper. Maintain suction on the syringe until dark red blood flows easily into the syringe.
- 6. Using the 18-gauge 2½-inch needle mounted on a 5- or 10-mL syringe, insert to parallel the seeker needle to enter the subclavian vein. The position of this needle should be identical to that of the seeker needle (i.e., the same direction, depth, and angle of penetration). Insert while aspirating with the syringe plunger. Placement within the vein is confirmed by easy return of dark red blood. Rotate the syringe/needle unit until the bevel of the needle faces caudally.
- 7. In many central line kits, a Raulerson syringe, which is an 18-gauge port that runs through the plunger and right out through the needle, is provided. This syringe allows guidewire insertion directly into the vein from the syringe plunger and allows the needle/syringe unit to be left in place where the subclavian vein was entered, thus minimizing the risk of unintentional movement of the needle out of the vein. If you do not have a kit with the plunger port, you will need to remove the syringe from the 18-gauge 2½-inch needle hub, making sure the needle does not move from its position. Occlude the needle hub with your nondominant thumb.

**EDITOR'S NOTE:** An intended benefit of use of a blue Raulerson syringe is the ability to differentiate arterial from venous blood by its color in the syringe. However, in patients with certain conditions (e.g., severe hypoxia, shock), arterial blood can be dark and mimic venous blood with adverse consequences. By disconnecting the introducer needle from the syringe, the clinician can determine whether the blood is pulsatile (arterial)

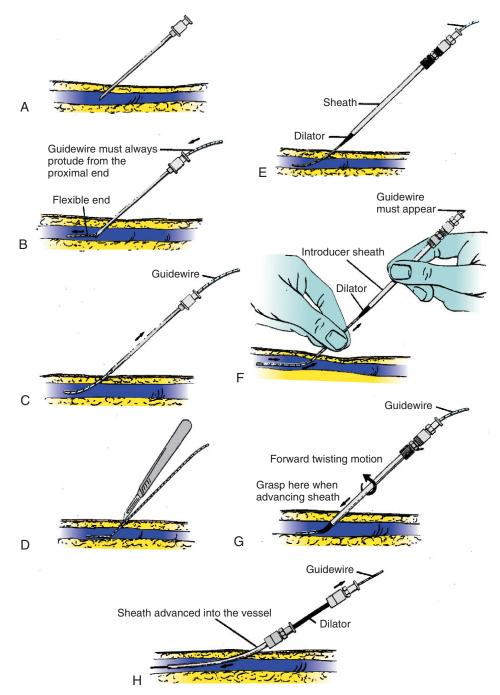

Figure 211-4 Placement of Seldinger-type guidewire and catheter. **A,** Introducing needle with tip in lumen. **B,** Advance guidewire into vein. **C,** Remove introducing needle over guidewire. **D,** Make small skin incision. **E,** Advance dilator and sheath until tip is near skin. **F,** If guidewire tip cannot be grasped, withdraw it slightly from the vein by grasping below the dilator tip. **G,** Advance dilator and sheath along guidewire and into vein. **H,** After sheath is fully advanced, slowly withdraw dilator and then guidewire. Immediately cover catheter hub with finger and attach to intravenous tubing. Also see text for details. (Modified from Roberts JR, Hedges JR [eds]: Clinical Procedures in Emergency Medicine, 3rd ed. Philadelphia, WB Saunders, 1998.)

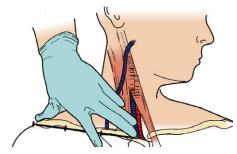

- or not. If there is any question, a sterile arterial blood gas syringe can be dropped into the field and a sample sent immediately for blood gas analysis. Make sure to cap the introducer needle hub while waiting for the result.
- 8. Insert the guidewire through the needle hub or plunger port. Most guidewires have a J loop at the end; straighten the loop by withdrawing the wire into its sheath. Then, once the straightened end of the wire is inserted into the needle, advance the guidewire approximately one half of its length into the subclavian vein.
- Withdraw, over the wire, the introducer needle/syringe unit. Make sure the wire stays steady and does not advance inadvertently its entire length into the vein, where it could embolize.
- 10. Using the no. 11 scalpel blade, to make room for the dilator and introducer sheath, make a small nick in the skin where the guidewire enters; it is easiest just to slide the blade on top of the wire.
- 11. Slide the dilator over the wire, and insert/withdraw the dilator several times to dilate the entry site tissues. Using a twisting motion while inserting the dilator may facilitate its advance. Withdraw the dilator over the guidewire and set it aside.

- 12. If color-coded, remove the *brown hub* from the central venous catheter. In some kits, the catheter is stiff enough to be inserted alone, directly over the guidewire. Otherwise, insert the dilator into the catheter (or some kits have a smaller diameter introducer that fits into the catheter to stiffen it). Slide the catheter (and dilator/introducer if needed, as a unit) over the wire, and advance the guidewire *up into the catheter* until it just pokes out of the open port. Holding the end of the wire, slide the catheter (and dilator/introducer if needed) down over the wire to the desired depth of insertion. Using a twisting motion when advancing the catheter may facilitate its advance.
- 13. Remove the dilator/introducer over the guidewire and then remove the guidewire and set aside. This leaves the catheter in place.
- 14. Secure the catheter to the skin with a suture (most kits have a plastic hub that fits over the catheter and has preformed suture holes for securing to the skin). The insertion area and exposed catheter should be covered with a sterile dressing (a clear bioocclusive dressing such as Tegaderm or Opsite provides added security).
- 15. Reattach the brown hub, or the required clave-type hub, to the catheter port, and aspirate each port to ensure easy blood return. Flush all ports with saline. You may hook up any IV tubing/ fluids at this time.
- Obtain a postinsertion chest radiograph to ensure that there is no iatrogenic pneumothorax and to check the catheter tip location.
- 17. If the catheter tip lies within the right atrium or ventricle, the catheter should be withdrawn so that the tip resides within the superior vena cava.

#### Infraclavicular Approach to the Subclavian Vein

This approach is very familiar because of the easily identified anatomic landmarks.

- 1. Position the patient in a moderate Trendelenburg position, as illustrated in Figure 211-2.
- 2. Orient yourself regarding landmarks, and establish an insertion site (Fig. 211-5). Place the thumb of your *nondominant* hand on the distal end of the clavicle and the middle finger of the same hand on the sternoclavicular joint. Let the index finger extend comfortably. The site for insertion will be immediately *under* the index finger, where it crosses the clavicle. Mark this site with your fingernail or a marker pen.
- 3. Open the central line catheter kit, wash your hands, don personal gear (mask, cap, eye protection, sterile gown, and gloves), and prep and drape the area in the usual fashion. Observe universal blood and body fluid precautions.
- 4. Using a 3-mL syringe with a 25-gauge needle attached, draw up 2 mL of 1% plain lidocaine and use this to anesthetize the insertion area. Infiltrate anesthesia into the deeper tissues under the clavicle as well.

**Figure 211-5** Orientation for subclavian catheter insertion, infraclavicular approach. Thumb of nondominant hand is on distal clavicle, middle finger on sternoclavicular joint.

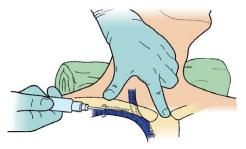

Figure 211-6 Inserting the seeker needle.

- Have patient turn his or her head contralaterally, or have an assistant hold the head rotated contralaterally.
- 6. Use the 3-mL syringe with the 22-gauge needle as a "seeker" needle. Position the thumb of your nondominant hand over your mark and place the index finger of the same hand between the two clavicular heads in the suprasternal notch. Insert the seeker needle 1 to 2 cm *inferior* to the clavicle. Aim for the suprasternal notch (Fig. 211-6). Keep the shaft of the seeker needle in contact with the inferior border of the clavicle as you work it under the clavicle. Aspirate as you go; entry into the subclavian vein is confirmed by the easy return of dark venous blood into the syringe. If the first attempt is unsuccessful, withdraw the seeker needle, flush it, confirm landmarks, and reinsert it under the clavicle, directing the needle *somewhat cephalad and deeper*. At times, the 1½-inch "seeker" needle will be too short to enter the subclavian vein with the infraclavicular approach.
- 7. Once the subclavian vein has been located, remove the seeker needle. Using the 18-gauge 2½-inch needle on a 5-mL syringe, insert it along the track of the seeker needle (i.e., the same direction, angle, and depth of penetration) to enter the subclavian vein. Entry is confirmed by the easy return of dark red blood into the syringe. Once in the vein, roll the syringe, so that the bevel of the needle is directed inferiorly.
- 8. If the 5-mL syringe has a plunger entry port, insert the guidewire through the port and into the vein. Leave one third of the wire's length free, and maintain control of this end with your dominant hand. If the 5-mL syringe does not have a plunger entry port, remove the syringe from the needle hub, and occlude the needle hub with your nondominant thumb until you insert the guidewire. If you do not have to traverse the syringe's length, leave one half of the guidewire free and secured.
- 9. Using your nondominant hand, remove the syringe/needle assembly, gliding it along the guidewire. Be sure to maintain the position of the guidewire in the superior vena cava.
- 10. Nick the skin with the no. 11 scalpel blade by following the guidewire as it courses into the deeper tissues.
- 11. Slide the dilator over the guidewire, and run it along the guidewire into the subclavian vein up to the hub. Using a twisting motion while inserting the dilator may facilitate its advance. Continue to maintain control of the guidewire. Remove the dilator by sliding it out of the vein and off the guidewire.
- 12. Remove the central venous catheter from the kit, and if color coded, remove the *brown* port hub. In some kits, the catheter is stiff enough to be inserted alone, directly over the guidewire. Otherwise, insert the dilator into the catheter (or some kits have a smaller diameter introducer that fits into the catheter to stiffen it). Slide the catheter (and dilator/introducer if needed, as a unit) over the guidewire, and advance the guidewire *up into the catheter* until it just pokes out of the open port. Holding the end of the wire, slide the catheter and dilator/introducer down over the wire to the desired depth of insertion into the vein. Using a twisting motion when advancing the catheter may facilitate its advance. Leave 2 to 3 inches of the catheter free; otherwise the catheter will traverse too deeply into the heart. Secure the position of the catheter with your nondominant hand.

- 13. Remove the dilator/introducer over the guidewire and then remove the guidewire, pulling it free from the catheter. This leaves the catheter in place. Aspirate just to ensure that the catheter tip is in the superior vena cava; this is confirmed by the easy return of dark red blood into the syringe. Attach a flush syringe to the brown port, and flush with 5 to 10 mL of saline.
- 14. Remove the flush syringe, and hook up the IV line or clave-type connector.
- 15. Secure the catheter with a silk skin suture, and cover any exposed catheter with a sterile dressing.
- 16. Obtain an immediate chest radiograph to confirm position of catheter in the superior vena cava and to ensure that no pneumothorax was created during catheter insertion. You can always back the catheter out an inch or two if it is too deeply inserted into the right atrium. Ideally, the catheter tip should lie in the superior vena cava, just above the right atrium.

**NOTE:** Occasionally, the subclavian artery may be entered during placement of the catheter. This is marked by a rush of bright red arterial blood into the syringe or out of the needle hub. If this occurs, withdraw all needles, and place pressure over the site for 10 minutes. Obtain an urgent radiograph of the chest to check for pneumothorax/ hemothorax, and check the distal arm pulse frequently. Recheck the hematocrit in 1 hour, and choose another site for venous access. If the catheter is seen to loop up the ipsilateral jugular vein, contralateral innominate vein, or contralateral subclavian vein on postplacement radiograph, the catheter will need repositioning. Because the sterile field has been removed, repositioning the catheter will involve a rewiring procedure. This procedure involves withdrawing the catheter until the tip lies just outside the ipsilateral jugular or innominate vein and then threading a sterile wire through the brown port of the preexisting catheter. The preexisting catheter is then removed leaving the wire in place and a new sterile catheter is introduced over wire using the Seldinger technique. Care must be taken to keep the wire sterile while discontinuing the "old" catheter.

#### **Internal Jugular Vein Catheterization**

Advantages of the internal jugular technique include the ability to cannulate the vessel during ongoing CPR and a relatively low iatrogenic complication rate. Bleeding complications are easily controlled by direct compression; hence this is the preferred approach for those patients who have a concurrent coagulopathy. Disadvantages include limited neck motion of the patient after insertion and injuries to the recurrent laryngeal nerve, phrenic nerve, and brachial plexus during insertion. A rare complication is ipsilateral pneumothorax. The central approach to internal jugular vein catheterization is described here:

- 1. Prepare the central catheter kit for use.
- 2. Position the patient as in Figure 211-2. Review the relevant anatomy, remembering that the internal jugular vein appears just under the triangular apex formed by the sternocleidomastoid muscle as it splits into sternal and clavicular heads. The vein then runs closely along the anterior border of the clavicular head of the sternocleidomastoid muscle and is lateral to the carotid artery.
- Prep and drape the area to define a sterile field, and don mask, cap, eye protection, sterile gloves, and gown. Maintain strict sterile technique from here onward. Observe universal blood and body fluid precautions.
- 4. Anesthetize with 1% lidocaine a 1- to 2-cm diameter area just caudal to the apex of the sternocleidomastoid muscle. Attach the 22-gauge seeker needle to the 3-mL syringe.
- 5. The insertion site is located just at, or slightly caudal to, the apex of the sternocleidomastoid triangle, in the anesthetized field. Insert the seeker needle; aim toward the *ipsilateral nipple* at a 30-degree angle. Entry to the vein is marked by the easy

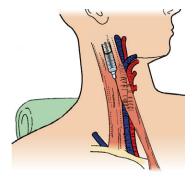

Figure 211-7 Needle approach to the internal jugular vein.

return of dark red blood into the syringe. Figure 211-7 shows the needle's approach to the vein.

- 6. Once the internal jugular vein has been located, remove the seeker needle. Using the 18-gauge 2½-inch needle on a 5-mL syringe, insert it along the track of the seeker needle (i.e., the same direction, angle, and depth of penetration) to enter the internal jugular vein. Entry is confirmed by the easy return of dark red blood into the syringe.
- 7. If the 5-mL syringe has a plunger entry port, insert the guidewire through the port and into the vein. Leave one third of the wire's length free, and maintain control of this end with your dominant hand. If the 5-mL syringe does not have a plunger entry port, remove the syringe from the needle hub, and occlude the needle hub with your nondominant thumb until you insert the guidewire. If you do not have to traverse the syringe's length, leave one half of the guidewire free and secured.
- 8. Using your nondominant hand, remove the syringe/needle assembly, gliding it along the guidewire. Be sure to maintain the position of the guidewire in the internal jugular vein.
- 9. Nick the skin with the no. 11 scalpel blade by following the guidewire as it courses into the deeper tissues.
- 10. Slide the dilator over the guidewire, and run it along the guidewire into the internal jugular vein up to the hub. Using a twisting motion while inserting the dilator may facilitate its advance. Continue to maintain control of the guidewire. Remove the dilator by sliding it out of the body and off the guidewire.
- 11. Remove the central venous catheter from the kit, and if color coded, remove the *brown* port hub. In some kits, the catheter is stiff enough to be inserted alone, directly over the guidewire. Otherwise, insert the dilator into the catheter (some kits have a smaller diameter introducer that fits into the catheter to stiffen it). Slide the catheter (and dilator/introducer if needed, as a unit) over the guidewire, and advance the guidewire *up into the catheter* until it just pokes out of the open port. Holding the end of the wire, slide the catheter and dilator/introducer down over the wire to the desired depth of insertion into the vein. Using a twisting motion when advancing the catheter may facilitate its advance. Leave 2 to 3 inches of the catheter free; otherwise the catheter will traverse too deeply into the heart. Secure the position of the catheter with your nondominant hand.
- 12. Remove the dilator/introducer over the guidewire and then remove the guidewire, pulling it free from the catheter. This leaves the catheter in place. Aspirate to ensure position of the catheter tip in the vein; this is confirmed by easy return of dark red blood into the syringe. Attach a flush syringe to the brown port, and flush with 5 to 10 mL of saline.
- Remove the flush syringe, and hook up the IV line or clave-type connector.
- 14. Secure catheter with a silk skin suture, and cover any exposed catheter with a plastic film dressing.
- 15. Obtain an immediate chest radiograph to confirm position of catheter in the superior vena cava, and to ensure that no pneu-

mothorax was created during catheter insertion. You can always withdraw the catheter an inch or two if it is too deeply inserted into the right atrium. Ideally, the catheter tip should lie in the superior vena cava just above the right atrium.

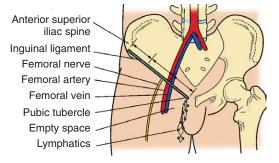

#### **Femoral Vein Catheterization**

Femoral vein catheterization is an alternative route to access the central venous system. Like the methods discussed previously, femoral vein catheterization may be used to deliver large volumes of fluid, chemotherapeutic agents, or total parenteral nutrition. By converting a femoral venous catheter to a percutaneous sheath introducer, a transvenous pacing wire or a Swan-Ganz catheter may be inserted. The femoral vein is easier to cannulate than the internal jugular or subclavian veins, and is readily accessible during CPR or other resuscitation. The few disadvantages to a femoral approach include the difficulty in sterilizing the groin insertion site, keeping it clean once the line is inserted, the increased risk of catheter-related venous thrombosis, and the fact that it limits patient mobility if the patient is ambulatory.

Contraindications to femoral line insertion include ipsilateral groin surgery or cellulitis over the proposed insertion site; a prosthetic vascular graft on the side of the proposed insertion; veno-occlusive diseases of the extremities or femoral venous thrombosis; and any uncontrolled bleeding diathesis. Because of the relatively superficial location of the femoral vein, direct pressure may be readily applied if required, and this author recommends this approach for those patients who are anticoagulated and require rapid central venous access.

Review the relevant anatomy in Figure 211-8. Note the neuro-vascular structures run in the following sequence from lateral to medial: nerve, artery, vein, "empty space," and lymphatics. The insertion site for femoral vein catheterization is just inferior to the femoral ligament, and 1 to 1.5 cm medial to the femoral artery, whose palpable pulse forms an important landmark for this procedure.

- 1. The patient should be flat in the supine position or in slight reverse Trendelenburg position. (The Trendelenburg position is contraindicated for this route of access due to the risk of venous air embolism.)
- 2. Set up the central venous catheter kit.
- 3. Wash hands and don mask, cap, eye protection, sterile gown, and gloves. Observe universal blood and body fluid precautions.
- 4. Prep and drape the groin area to obtain a sterile field. In obese persons, you may need an assistant to hold back any redundant pannus from the groin area in order to gain access to the femoral vein.
- 5. Locate the femoral pulse with fingers of your nondominant hand.
- Using the 25-gauge needle on a 3-mL syringe, draw up 3 mL of lidocaine and anesthetize the area just medial to the femoral artery.

**Figure 211-8** Relevant anatomy of groin showing relationship of femoral vein to surrounding structures.

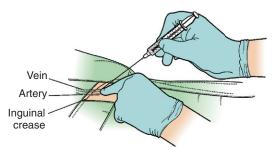

Figure 211-9 Approach to femoral vein cannulation.

- 7. You may use the 22-gauge needle on a 3-mL syringe as a seeker, or proceed directly with the 2½-inch 18-gauge needle on the 5-mL syringe with plunger port to find the femoral vein. Refer to Figure 211-9 for the approach to cannulation. With bevel down, angle the needle at 30 degrees to the skin, and aim at the ipsilateral nipple. Aspirate as you insert the needle. Entry into the femoral vein is marked by the easy return of dark red blood into the syringe. Once a free flow of blood is verified, stop advancing the needle.
- 8. Stabilize the 2½-inch needle and syringe assembly with your nondominant hand. If the syringe has a plunger port, pass the guidewire down this port, feeding approximately one half of the wire into the femoral vein. If there is no plunger port, carefully rotate the syringe off the needle hub, and advance the guidewire into the vein.
- 9. Maintain control of the distal end of the guidewire with your dominant hand, and remove the 2½-inch needle/syringe assembly over the wire with your nondominant hand.
- 10. Nick the skin at the entry site of the guidewire with the no. 11 scalpel blade. Thread the dilator over the guidewire, and run it into the groin several times to create a passage for the central venous catheter assembly. Maintain control of the distal end of the guidewire at all times.
- 11. Remove the dilator over the guidewire. If color coded, remove the *brown* hub from the central venous catheter. In some kits, the catheter is stiff enough to be inserted alone, directly over the guidewire. Otherwise, insert the dilator into the catheter (or some kits have a smaller diameter introducer that fits into the catheter to stiffen it). Slide the catheter and dilator/introducer as a unit over the wire, and advance the guidewire *up into the catheter* until it just pokes out of the open port. Holding the end of the wire, thread the catheter and dilator/introducer as a unit over the guidewire. Using a twisting motion when advancing the catheter may facilitate its advance. Advance the catheter over the wire until the catheter is fully within the femoral vein.
- 12. Remove the dilator/introducer over the guidewire and then remove the guidewire; this leaves the catheter in place. Stabilize the catheter with a free hand while the guidewire is pulled out.
- 13. Suture the catheter in place with a silk suture, and flush all catheter ports with saline; clave hubs may be attached at this time. Cover the insertion site with a sterile dressing.
- 14. Some practitioners may elect to perform an abdominal flat plate radiograph at this time to ensure placement of the catheter in the common iliac vein.
- 15. Lastly, some practitioners elect to give a dose of a broadspectrum antibiotic at this time (although there is no evidence to support this practice).

#### **COMPLICATIONS**

- Thrombosis of the vein
- Hemorrhage or hematoma at the insertion site

#### 1450 HOSPITALIST

- Local, systemic, or catheter-related infection (often from poor sterile technique, but not always)
- Hydrothorax from infusion of IV fluids into the chest cavity from erroneous placement of a catheter using subclavian or internal jugular approach
- Tracheal perforation
- · Perforation of an endotracheal tube cuff
- Air embolus (usually with subclavian or internal jugular vein catheter insertion if patient was not placed in Trendelenburg position prior to vein cannulation)
- Guidewire fragment embolus (results from shear of guidewire when it is pulled back out of insertion needle)
- Lost guidewire
- · Laceration of a lymphatic duct
- Arteriovenous fistula
- Superior vena caval obstruction
- Pericardial tamponade
- Injury to local nerve structures
- Catheter malposition (a catheter inserted into the subclavian or internal jugular vein may thread itself back up into the neck or the arm)
- Catheter kinking
- Cardiac dysrhythmias

# TUBE THORACOSTOMY AND EMERGENCY NEEDLE DECOMPRESSION OF TENSION PNEUMOTHORAX

Scott Savage

Tube thoracostomy, or chest tube insertion, is performed to evacuate air or fluid from the pleural space. A related procedure, emergency needle decompression, is performed to relieve a tension pneumothorax. Tension pneumothorax is a life-threatening condition. Air progressively accumulates in the pleural space, eventually compressing the lung and the mediastinum, causing decreased blood flow in the great vessels and subsequent death. Patients with tension pneumothorax present with dyspnea, tachycardia, and hypoxia. Jugular venous distention and midline tracheal shift are classically described but rarely present. Hypotension is an ominous sign that signifies obstructive shock.

The radiographic features of a tension pneumothorax are a 100% pneumothorax with a midline shift away from the collapsed lung. However, if clinically suspected, an emergency needle decompression should be performed; to wait for a confirming chest radiograph is unnecessary. A preprocedure chest radiograph should be obtained only in stable patients in whom the diagnosis is in question.

Diagnosing a tension pneumothorax in infants may be difficult because lobar emphysema can mimic a pneumothorax. Making the correct diagnosis is essential because chest tube insertion in the presence of lobar emphysema can make the infant worse. If the infant is hemodynamically stable, it is advisable to get three radiographic views of the chest—lateral, anteroposterior (AP), and lateral decubitus with the affected side inferior. A specialist in radiology, pediatrics, or pediatric emergency medicine should be consulted to help with film interpretation.

#### **EMERGENCY NEEDLE DECOMPRESSION**

#### Indication

Tension pneumothorax indicates the need for emergency needle decompression.

#### Contraindication

Lobar emphysema in infants is a relative contraindication.

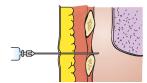

#### **Equipment**

- Antiseptic solution (e.g., povidone–iodine, chlorhexidine)
- Sterile hemostat

- 10-mL syringe half-filled with 2% lidocaine with epinephrine (or equivalent) attached to a large-bore (18-gauge or larger), 2-inch catheter-over-needle (angiocatheter)
- Supplemental oxygen, continuous cardiac and blood pressure monitoring

#### **Technique**

- 1. Place the patient in the semiupright position (head of bed elevated to 30 to 60 degrees).
- 2. Provide supplemental oxygen. If available, continuous cardiac and blood pressure monitoring is helpful.
- Obtain rapid verbal consent with a witness present, if possible.
- 4. Apply antiseptic solution to a generous area of the second intercostal space where a line drawn laterally from the level of the sternomanubrial junction (Lewis's line) would intersect a line drawn down from the mid-clavicle (mid-clavicular line)
- 5. Locate the *upper border* of the rib at this intersection.
- 6. Insert the catheter-over-needle perpendicular to the skin just above the upper border of the rib (Fig. 212-1). (Remember that the neurovascular bundle runs below the ribs.) Once through the skin, infiltrate the tissue with half of the anesthetic solution
- 7. Before proceeding further, attempt aspiration. If air is obtained, then the catheter-over-needle is not secured to the syringe tightly enough. Use the hemostat to tighten the catheter hub on the syringe before advancing the catheter-over-needle any farther.
- 8. After creating the skin wheal and testing the seal, advance the catheter-over-needle at a moderate rate with continuous aspiration until air is obtained—this will be noted by bubbles in the syringe and easy aspiration.
- 9. Advance the catheter-over-needle an additional half centimeter to prevent accidental dislodgement.
- 10. Using the hemostat, unscrew the syringe to allow free passage of air. *Do not* hook up the needle to suction. The air in the thoracic cavity is under pressure (under tension) and will exit the needle spontaneously; it should gush out. Intrathoracic pressure will equilibrate with room air, which is acceptable until tube thoracostomy is placed.

**Figure 212-1** Placement of a catheter within a needle. Insert the needle slightly above the rib, and air should return or express itself through the needle.

11. Do not remove the needle at this point. In older texts, it was advised to remove the needle because the plastics in older catheters were much harder than the soft Silastic catheters now used. Unlike the older catheters, the new catheters are too soft to endure the tissue pressure of the intercostal muscles and will rapidly collapse, causing reaccumulation of the tension pneumothorax. Concerns that the re-expanding lung will be impaled on and lacerated by the needle (pulmonary laceration) are generally unfounded. There is a 100% pneumothorax present, and it is unlikely that lung tissue is near the needle tip so long as suction is not used. The purpose of this procedure is to relieve excessive intrathoracic pressure and allow blood circulation. Subsequent tube thoracostomy, hopefully performed very soon after emergency needle decompression, will provide full lung re-expansion. The time to remove the catheter-over-needle (angiocatheter) is just prior to applying suction to the chest tube.

**EDITOR'S NOTE:** In one ultrasound study (Ball and collegues, 2010), a 1½-inch-long catheter-over-needle would fail to reach the pleural space in 65% of adults; however, a 1½-inch catheter-over needle should reach the pleural space in 96% of adults.

#### **TUBE THORACOSTOMY**

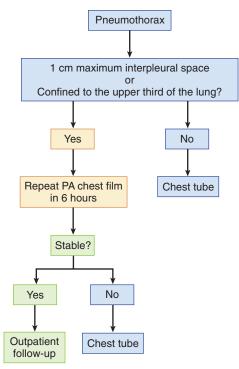

#### **Indications**

- Pneumothorax
- After needle decompression of a tension pneumothorax
- Chylothorax
- Empyema
- Hemothorax
- Malignant pleural effusion
- Pleurodesis
- Recurrent pleural effusion
- Prevention of a hydrothorax after thoracotomy (cardiothoracic or lung resection surgery)

#### **Contraindications**

- No contraindications if the procedure is emergent.
- Bleeding dyscrasia.
- Severe thrombocytopenia (platelet count <50,000 cells/mL relative contraindication).
- Bullae (relative contraindication).
- Conditions causing pleural scarring in the area of planned insertion.
- Empyema with acid-fast organisms.
- History of pleurodesis.
- Use caution if loculated fluid collections are present.
- Pneumothorax of less than 20% that is stable for 6 hours (Fig. 212-2).
- Known or suspected mesothelioma.

There are many methods to determine whether or not a pneumothorax is greater than 20%. One method is to use the "1 cm and one third rule": if a pneumothorax creates no more than 1 cm distance between the pleural line and the inner chest wall and is also confined to the upper one third of the chest on an AP upright radiograph, then the pneumothorax is less than 20%. These may

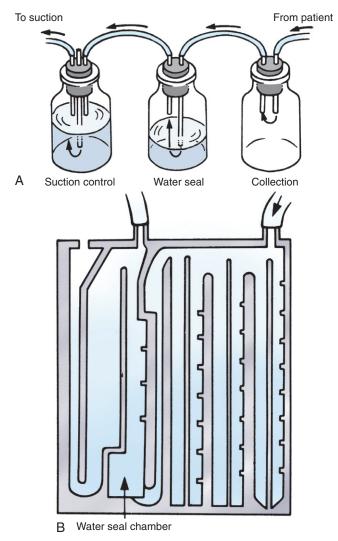

**Figure 212-2** Algorithm used for deciding necessity of thoracostomy. PA, posteroanterior.

resolve without any intervention (see Fig. 212-2). Stability is gauged by comparing a chest radiograph taken initially to one obtained 6 hours later. Although it may require thoracostomy, a simple pneumothorax is the accumulation of air, not under pressure, within the pleural space.

Results from some studies suggest that mere aspiration of a simple pneumothorax can be performed without placing a chest tube. However, this method is still controversial, because other studies indicate little better than a 50% success rate. The success rate may be higher in carefully selected patients.

#### Equipment

- Adhesive tape (Tensoplast or Elastoplast preferred)
- Antiseptic solution (e.g., povidone–iodine, chlorhexidine)
- Chest tube (alternatives are Seldinger guidewire kit or catheterover-needle kit; Heimlich valve can be attached)
- Connector (5-in-1, also known as Christmas tree connector)
- Local anesthetic
- Petroleum impregnated gauze
- Sterile drapes
- Sterile gown and gloves
- Suction-drainage system (Fig. 212-3)
- Surgical mask, cap, and goggles
- Wall suction unit
- Supplemental oxygen, pulse oximetry, continuous cardiac and blood pressure monitoring
- Thoracostomy tray
  - 4 sterile towels
  - 1 package 4 × 4 inch sterile gauze pads
  - 4 towel clips (optional)
  - 1 large straight scissors
  - 1 large curved (Mayo) scissors
  - 2 large curved (Kelly) clamps
  - 2 medium-sized clamps
  - 1 needle holder
  - 1 package of 2-0 to 4-0 nonabsorbable suture
  - 1 no. 11 or no. 10 scalpel mounted onto a holder

**Figure 212-3 A,** Three-bottle system: first bottle (*right*) is the collection chamber; second bottle (*center*) is the water seal; third bottle (*left*), closest to wall suction, is the suction control chamber. **B,** Disposable suction unit.

NOTE: Trocars have a high complication rate and should not be used.

Adult tube size selection

- Primary spontaneous pneumothorax: 7 F to 14 F
- Secondary spontaneous pneumothorax: 20 F to 28 F
- Trauma, mechanical ventilation, or detectable pleural fluid: 28 F to 40 F

Secondary spontaneous pneumothoraces are associated with underlying lung diseases such as chronic obstructive pulmonary disease (COPD), asthma, cystic fibrosis, infection, interstitial lung disease, neoplasms, connective tissue disease, pulmonary infarction, and endometriosis.

#### **PROCEDURES**

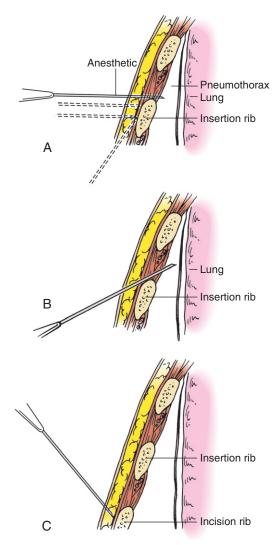

#### **Initial Preparation (for All Techniques)**

- Obtain written informed consent if possible. Patient should be aware of the indications, risks, and complications of the procedure, and whether any alternatives exist.
- 2. Because the procedure can be rather painful, the patient should be warned and prepared, even if a local anesthetic is used.

- Procedural sedation is recommended (see Chapter 2, Procedural Sedation and Analgesia). If time allows, obtain a partial thromboplastin time (PTT), international normalized ratio (INR), and platelet count.
- 3. Place the patient on 100% oxygen. (Use of oxygen increases the resorption rate of pneumothorax by fourfold.)
- 4. Monitor the patient with pulse oximetry and continuous cardiac and blood pressure monitoring.
- 5. An ultrasound (see Chapter 225, Emergency Department, Hospitalist, and Office Ultrasonography [Clinical Ultrasonography]) may be helpful for localizing the air or fluid levels and for possibly excluding any anatomic variants that could place the patient at risk.
- Assemble the suction-drainage system according to the manufacturer's recommendations.
- 7. Connect the suction-drainage system to suction.
- 8. Create a sterile field for the equipment.
- Measure the length of tube to be inserted: from the mid-axillary line at the fifth intercostal space to the inferior tip of the scapula. A piece of suture with the needle removed is often used to make this measurement.
- 10. In a sterile manner, open the package containing the tube and occlude the distal end at the properly measured distance with a large sterile clamp.
- 11. The distal end (usually beveled) of the tube can be cut so that it is "squared off," if needed to ensure a firm connection.
- 12. Place the patient in the semiupright position with the ipsilateral arm placed overhead and the wrist secured with a soft restraint. Use standard restraint monitoring.
- Maintain sterile technique, including use of face mask, gown, and sterile gloves, and observe universal blood and body fluid precautions.
- 14. Mark the fifth intercostal space just slightly anterior to the midaxillary line. In males, this is generally one space below the nipple line. In females, it is generally two fingerbreadths above the base (not the tip) of the xiphoid. Although an anterior approach was used in the past for pure pneumothoraces, it has fallen out of favor. (Studies have failed to demonstrate a significant clinical advantage and this approach leads to worse cosmetic results.) The posterior approach is generally reserved for thoracentesis.
- 15. Prepare the incision site area with antiseptic solution, and drape to create an adequate sterile field.
- 16. In a sterile fashion, infiltrate the skin with 2 to 4 mL of lidocaine 2% with epinephrine or equivalent local anesthesia at the *incision* site. Be careful to insert the needle just above the upper border of the rib. This avoids damage to the neurovascular bundle, which lies in a groove at the lower border of the ribs. Then use up to 6.5 mg/kg lidocaine with epinephrine (1 mL of 2% lidocaine contains 20 mg of lidocaine) to anesthetize the deeper structures along the tract that the chest tube will traverse and enter the pleural space (Fig. 212-4 shows a Z-tract technique).

#### **Seldinger Guidewire Technique**

- 1. Prepare as directed in "Initial Preparation" section.
- 2. The Seldinger guidewire technique requires use of a prepackaged kit, but it is generally preferred to the traditional open technique. For most operators, it is simpler, faster, and safer than the open technique. A Z-tract technique is unnecessary.
- 3. Open the kit and check the inventory to ensure all necessary materials are present and double check that the items listed on the package cover have been properly packaged. (Note that some kits do not include the ancillaries [cleaning swabs, tape, lidocaine for anesthetic].)
- 4. Using the locator needle, insert the tip just above the top of the rib in the anesthetized area, slowly advance the needle

**Figure 212-4** Infiltration of the skin, subcutaneous muscle, and periosteum of the rib (**A**); the pleura (**B**); and skin incision site (**C**) with local anesthetic.

- perpendicular to the thorax, and enter the pleural cavity while aspirating for air, blood, or other fluid (similar to Fig. 212-1).
- Once air, blood, or fluid is obtained, feed the guidewire posteriorly and superiorly toward the scapula in adults or anteriorly and superiorly toward the manubrium or sternal notch in small children.
- Maintaining manual control of the guidewire at all times, remove the locator needle and nick the skin in a direction parallel to the rib with an 11-blade scalpel to about one third the depth of the scalpel.
- 7. Feed the smallest dilator over the guidewire with a twisting motion, and once through the skin, aim toward the tip of the scapula in adults and the sternal notch in small children.
- 8. If progressive dilators are available, use these to gradually widen the insertion track.
- 9. Remove the dilators and insert the chest tube over the guidewire to the premeasured length.
- 10. Remove the guidewire.
- 11. Attach the chest tube to the suction-drainage system. Be careful when removing the distal clamp, as blood or fluid may flow forcefully from the tube.
- 12. Have the patient cough, and check for bubbles in the water seal, which indicates good flow. (A Heimlich valve may then be used for a simple pneumothorax and no recurrent leaking.)

- 13. Secure the tube with tape (Tensoplast or Elastoplast tape is preferred; avoid taping the nipple), and obtain a chest radiograph. Suturing is not absolutely necessary, although it is recommended to ensure that the tube does not get dislodged. Likewise, petroleum gauze is not absolutely required unless an air leak is identified.
- 14. If no adjustment is needed, then tape the suction connector to the tube.
- 15. Consider use of prophylactic antibiotics.

# Using Pneumothorax Evacuation Kits (Catheter-over-Needle, Heimlich Valve)

- Special kits containing a single catheter-over-needle device, a connector, and a Heimlich valve are now available. They are used only in simple pneumothoraces but are very convenient and effective for that process.
- 2. Prepare as directed in the "Initial Preparation" section. Enter the interspace using the locator needle. Remove the needle.
- 3. Insert the catheter-over-needle tip just above the top of the rib in the anesthetized area, slowly advance the needle perpendicular to the thorax, and enter the pleural cavity while aspirating for air (similar to Fig. 212-1).
- 4. Once air is obtained, the catheter is advanced, the needle removed, and the Heimlich valve connected.
- The Heimlich valve is taped to the anterior chest wall. This reduces the chance of the patient accidentally dislodging it with the elbow.
- 6. A postprocedure radiograph is required.
- Although clinical judgment is required, it has been suggested that many patients receiving these types of devices may be discharged for next day follow-up.

#### Traditional (Open) Technique

- 1. Prepare as directed in "Initial Preparation" section.
- 2. At the fifth intercostal space in the mid-axillary line where the lower skin wheal was anesthetized, create a 2- to 4-cm skin incision (approximately two fingerbreadths) that follows the rib (Fig. 212-5).
- Using a curved Kelly clamp, bluntly dissect until bone or muscle fascia is reached.
- From this position, change the direction of the dissection superiorly, with the tips of the clamp directed upward, until the

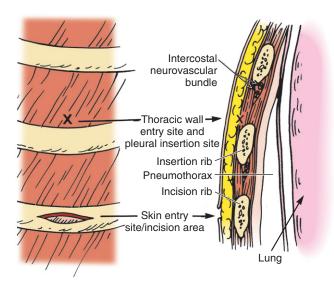

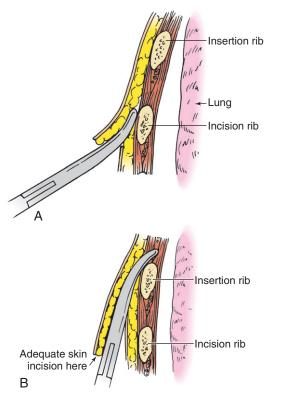

Figure 212-5 Skin incision is made one rib below the rib over which the tube will pass. Location of the intercostal neurovascular bundle is shown.

**Figure 212-6 A** and **B**, Tunneling procedure diagram that forms a Z-tract. (See text for details.)

upper border of the next rib is reached (Fig. 212-6). This should be at the level of the second anesthetic wheal.

- 5. From that position, rotate the tip of the curved clamp inward and use it to push through the intercostal muscle and parietal pleura. A popping sensation is often felt. (Do not push the clamp too far into the pleural space where it could cause damage to the great vessels, heart, diaphragm, or lungs.)
- 6. Once inside the pleural space, open the clamp and withdraw partially to widen the space. Be careful not to withdraw completely, as you may then lose the opening and therefore have to begin again.
- 7. Using the other hand, place a gloved finger in the pleural space (Fig. 212-7) as you withdraw the open curved clamp completely.

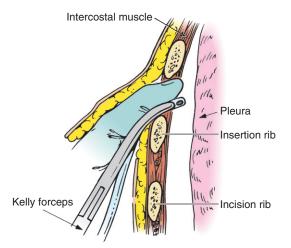

Figure 212-7 Tip placement in the pleural cavity, using the finger as a guide.

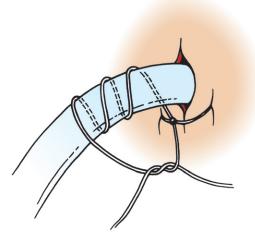

Figure 212-8 Chest tube is fastened with a stay suture.

The idea is to keep either the clamp or your finger in the hole at all times to prevent losing the opening.

- 8. Sweep the finger to confirm proper placement (you should not feel the diaphragm) and to detect any adhesions.
- 9. Using the curved clamp, grasp the proximal end of the tube (fenestrated end) and guide the tube into the pleural space, withdrawing your finger as you do so. Again, the idea is to keep either your finger or the tube in the hole at all times to prevent losing the opening.
- 10. Connect the tube to the suction-drainage system. Be careful when opening the distal clamp, as blood or fluid may flow forcefully from the tube.
- 11. Attach the suction-drainage system to suction.
- 12. Have the patient cough, and check for bubbles in the water seal, which indicates a patent system.
- 13. Suture the tube in place, taking care not to puncture the tubing. A variety of techniques are acceptable. A common one is to use a single horizontal mattress suture to close the incision around the tube. After tying a knot, and before cutting the suture ends, wind one around the tube several times and back to tie to the other end (Fig. 212-8). Alternatively, a second suture can be placed through the skin; it is then wound around the tube several times and secured with a knot.
- 14. Wrap the tube with petroleum gauze and secure the tube with tape (avoid taping the nipple).
- 15. Obtain a chest radiograph. Remove the chest tube and insert a new one if it is kinked, bent, in the fissure of the lung, or in the subcutaneous tissues.
- 16. If no adjustment is needed, then tape the suction connector to the tube, and the tube to the patient's side. (Tensoplast or Elastoplast tape is preferred.)
- 17. Consider the use of prophylactic antibiotics.

#### **MANAGEMENT**

After the chest tube is inserted, it should be connected to the suction-drainage system. Suction should be maintained until there is no air leak. Although many different protocols exist as to when to consider removing the tube, the most prudent method is to turn off the suction after the patient's lung re-expands and allow the patient to remain on water seal for 6 to 12 hours to detect occult air leaks. Chest tube dressings should be changed every 24 hours, or sooner if the dressing becomes saturated.

A chest radiograph taken 4 to 6 hours after chest tube insertion should show improvement in the pulmonary condition. If the patient's condition is not improved, check for persistent bubbling in the system. If bubbling is present, then check the connections between the chest tube, connectors, and hosing throughout the system. If the air leak continues, place cloth tape over all the connections. Examine a chest radiograph to confirm that all fenestrations are within the thoracic cavity. If not, replace the tube (advancing the current chest tube may track infectious material into the pleural cavity). If the air leak persists, check the tubing for holes or cracks, and replace any damaged tubing. If the air leak continues, place a second chest tube and prepare the patient for thoracoscopy, bronchoscopy, or esophagoscopy to diagnose the etiology of the leak.

#### **CHEST TUBE REMOVAL**

#### **Indications**

- No air drainage for 24 hours
- Less than 150 mL fluid drainage in 24 hours

#### Contraindication

A persistent need for a chest tube contraindicates its removal.

#### **Equipment**

- Suture scissors
- Petroleum gauze
- Several sterile 4 × 4 inch gauze sponges
- Tape (Tensoplast or Elastoplast preferred)

#### Removal Technique

- If sutures were used to secure the tube during placement, cut the sutures.
- 2. Disconnect the tube from the suction-drainage system.
- If the patient is awake and cooperative, have the patient exhale and hold his or her breath. If the patient is nonalert and artificially ventilated, pause the ventilator in exhalation.
- 4. Swiftly and smoothly remove the tube.
- Apply petroleum gauze covered by sterile 4 × 4 inch gauze sponges.
- Apply a pressure dressing with tape (Tensoplast or Elastoplast preferred).
- 7. Repeat the chest radiograph in 6 to 12 hours.
- 8. Observe for complications.
- After 48 hours, the dressing may be removed. The patient should follow routine wound care instructions.

#### **COMPLICATIONS**

- Injury to the heart, great vessels, lung, diaphragm, liver, spleen, or even the intestines
- Subdiaphragmatic placement of tube
- Open pneumothorax
- Tension pneumothorax
- Dislodgement of the tube
- Subcutaneous emphysema
- Re-expansion pulmonary edema
- Unexplained or persistent air leakage
- Hemorrhage from an injured intercostal artery
- · Local or more generalized infection

#### **CPT/BILLING CODES**

- 32002 Thoracentesis with insertion of tube with or without water seal (e.g., for pneumothorax)
- 32020 Tube thoracostomy with or without water seal (e.g., for abscess, hemothorax, empyema)

#### **ICD-9-CM DIAGNOSTIC CODES**

- 011.7 Pneumothorax, tuberculous
- 012.0 Empyema, tuberculous
- 197.2 Pleura malignant or pleural effusion, malignant
- 457.8 Chylous hydrothorax
- 510.9 Empyema, without mention of fistula (use additional code to identify infectious organism [041.0 to 041.9])
- 511.1 Pleurisy with effusion, bacterial, nontuberculous
- 511.8 Hemothorax or hemopneumothorax
- 511.9 Pleural effusion, unspecified
- 512.0 Pneumothorax, tension, spontaneous
- 512.1 Pneumothorax, due to operative injury of chest wall or lung
- 512.8 Pneumothorax, spontaneous
- 772.8 Hemothorax, newborn
- 860.0 Pneumothorax, traumatic, without mention of open wound into thorax
- 860.2 Hemothorax, traumatic, without mention of open wound into thorax
- 860.4 Pneumohemothorax, traumatic, without mention of open wound into thorax

## TRACHEAL INTUBATION

Scott Savage

Airway emergencies can be some of the most daunting situations a practitioner encounters. Radical advances in airway management have been made and are reviewed here.

#### **INDICATIONS**

- Hypoxia
- Respiratory distress
- Protection of the airway
- Cardiopulmonary arrest
- Need to maintain hyperventilation (e.g., with traumatic brain injury)

#### **CONTRAINDICATIONS**

- Cervical spine injury (may use video and optical laryngoscopes, fiberoptic laryngoscope, or digital [tactile] technique)
- Cervical spine severely immobilized due to arthritis (may use video and optical laryngoscopes, fiberoptic laryngoscope, or digital [tactile] technique)
- Expanding neck hematoma (relative, must use caution but may require surgical airway)
- Uncontrolled oropharyngeal hemorrhage (relative, may require surgical airway)
- Intact tracheostomy or stoma (replace tracheostomy tube)
- Combative patient (consider rapid-sequence intubation [RSI] described in this chapter)
- Trismus (consider RSI or nasotracheal intubation)
- Severe facial or neck trauma (consider needle or surgical cricothyroidotomy; see Chapter 199, Cricothyroid Catheter Insertion, Cricothyroidotomy, and Tracheostomy)

#### **EQUIPMENT**

See Figure 213-1.

- Laryngoscope (and fresh batteries)
- Laryngoscope blades (at least two different types)
- Endotracheal tubes
  - Adult men sizes 7 to 9
  - Adult women sizes 6 to 8
  - Nasotracheal intubation sizes 5 to7
  - Pediatrics—consult Broselow tape or use the size equal to the width of the fingernail of the little finger. Use uncuffed tubes in infants and small children up to 8 years of age.
- Water-soluble lubricant
- 10-mL syringe
- Umbilical tape or endotracheal tube holding device
- Scissors
- Bag-valve-mask device (Ambu-bag) with 100% oxygen delivery system
- Pulse oximeter

- Capnograph, carbon dioxide detector, esophageal detector or other device to confirm tube placement
- Suction system with dental or Yankauer tip in children and adults, DeLee suction in neonates
- Stethoscope
- · Cardiac monitor and defibrillator
- Blood pressure monitor
- Gloves
- Face mask, goggles or eye shield, and any other equipment necessary to follow universal blood and body fluid precautions
- Intravenous line (if possible)
- Ventilator
- Cricothyroidotomy kit
- Sedative medication to use for chemical restraint (e.g., propofol, benzodiazepines)

#### CRICOID PRESSURE (SELLICK MANEUVER)

Providing or performing cricoid pressure may help protect against regurgitation of gastric contents; it also increases visibility by moving the trachea into the visual field of the person intubating. To perform cricoid pressure (Sellick maneuver), first find the thyroid cartilage (Adam's apple), and then the small indentation beneath it (cricothyroid membrane). The cartilage beneath this small indentation is the cricoid bone. Cricoid pressure is performed by pinching the extended thumb, index, and middle finger together into a double "V," or tripod. This is then placed on the cricoid bone and pressed down with enough pressure to occlude the esophagus (Fig. 213-2). The pressure should be applied toward the patient's back and the head somewhat. Cricoid pressure should not be released until intubation is completed and confirmed and the cuff inflated.

**NOTE:** The effectiveness of the Sellick maneuver has been questioned. Because of the wide variation in pressure applied by operators, cricoid pressure should be removed if there is difficulty in visualizing the airway.

#### **AIRWAY ASSESSMENT**

Begin with the patient on 100% nonrebreather mask if spontaneously breathing. The jaw thrust maneuver can be used to keep the airway open (Fig. 213-3), or begin bag-valve-mask breathing with a second assistant providing cricoid pressure (Sellick maneuver). The practitioner should be familiar with the anatomic landmarks (Fig. 213-4). Many airway management failures can be traced to lack of airway assessment. Patients can be classified into three groups (shades) based on two criteria: anticipated difficulty in intubation and ability to maintain oxygen saturation greater than 90% by bag-valve-mask ventilation. Airway assessment is critical. An experienced person can assess an airway in less than 4 seconds, and an inexperienced person should be able to do so in less than 8 seconds.

The mnemonic for assessing difficulty in intubation is 332-NUTS:

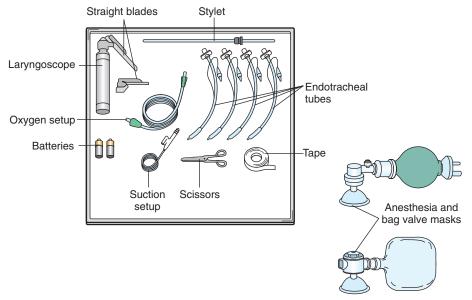

Figure 213-1 Suggested intubation equipment.

- 3—fingerbreadths, mouth opening
- 3—fingerbreadths, mentum (distance from the tip of the chin to the anterior soft tissue of the neck)
- 2—fingerbreadths, thyromental distance (distance from the top of the thyroid cartilage to the upper soft tissue angle of the neck)
- N—Normal neck flexion
- U—Uvula visible when opening the mouth
- T—no Tension pneumothorax
- S—no "Soup" (foreign body in the airway)

Meeting all these criteria indicates a low-risk intubation; conversely, the fewer the criteria present, the higher the risk. Although the last two categories, tension pneumothorax and "soup," do not strictly determine the anatomic difficulty of intubation, establishing their absence is a vital part of early airway assessment. The Mallampati system has previously been used to assess the uvular portion of the mnemonic; however, it is important to note that this classification

**Figure 213-2** Sellick maneuver. Either the practitioner or assistant uses the thumb and index and middle fingers pinched into a double "V" or tripod. Posterior pressure is then applied to the cricoid to avoid aspiration and bring the larynx into view. Note the upward and forward direction of forces applied in a nonfulcrum manner by the laryngoscope.

was designed to assess a patient sitting upright with voluntary mouth opening—a condition rarely encountered in clinical practice outside anesthesiology. A simpler method is to open the mouth with the thumb while standing to either side of the patient's head. (Standing at the head of the patient changes the angle of view, and may produce a false result). If any portion of the uvula can be seen, then intubation will likely be unimpeded by this factor. The three risk groups (shades) are as follows:

- Pink—able to keep the oxygen saturation greater than 90%; anticipate easy intubation and use standard technique.
- Purple—able to keep the oxygen saturation greater than 90%, but anticipate difficult intubation. Attempt awake laryngoscopy. If successful, perform an assisted intubation with a gum elastic bougie, intubating or fiberoptic laryngoscope, lighted stylet, or similar device. If not, use an intermediate airway (laryngeal mask airway [LMA] or King LTS-D) if possible, and obtain expert assistance for further management.
- Blue—unable to keep the oxygen saturation greater than 90%. If possible, perform a single attempt at an intermediate airway (LMA or King LTS-D). If successful and easy intubation is anticipated, attempt assisted intubation as in the purple patient. If difficulty is anticipated, obtain expert assistance for further management if time permits. If not, needle or surgical cricothyroidotomy may be needed.

**Figure 213-3** Jaw thrust. Rotate mandible forward with index fingers. Arrow indicates motion to bring soft tissues forward to relieve airway obstruction.

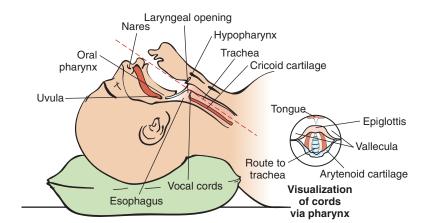

Figure 213-4 Anatomic landmarks of the head and neck.

#### STANDARD OROTRACHEAL INTUBATION

#### **Preparation**

Lack of proper preparation is another common reason for failure to intubate. If the airway risk is purple or blue, auxiliary techniques should be strongly considered. However, if the patient is classified in the pink group, attempt standard orotracheal intubation. Prepare for intubation using the mnemonic "airway START." The airway prefix distinguishes it from a similar mnemonic used for triage in mass disasters.

- S—Shade (classify the patient as pink, purple, or blue and select the proper technique)
- T—Technicians (respiratory technician and cricoid pressure technician)
- A—Assemble (ensure all the equipment and drugs are prepared)
- R—Respiration (preoxygenate with at least eight vital capacity breaths. If time permits, and the patient is breathing spontaneously, 5 minutes of preoxygenation provides 5 minutes of protection)
- T—Tilt (ensure both the patient and the practitioner are properly positioned)

#### **Technique**

The cricoid pressure technician should initiate cricoid pressure using the Sellick maneuver as soon as the respiratory therapist begins bagging. This will reduce stomach insufflation and the risk for vomitting. The cricoid pressure technician also watches the oxygen saturation of the patient and announces saturations below 90% to the practitioner. In addition, this technician holds the endotracheal tube and passes it to the practitioner so the practitioner can focus uninterrupted on the intubating view.

"Tilt" or position of the patient and the practitioner is often overlooked, but this is probably the most critical component of successful intubation. If the patient is not suspected of having neck problems that could be worsened by movement, place the patient in the "sniffing" position with the neck flexed and the head extended backward (Fig. 213-5). The neck may be flexed by raising the head several inches using a folded towel or firm pillow. It is important to remember that the padding should be placed under the head and not between the shoulders (see Fig. 213-4).

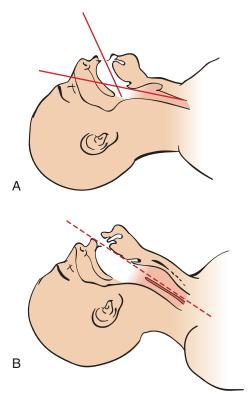

The position of the practitioner is even more important. The most common problem is having an angle of view that is too high to visualize the anatomy, which is caused by being both too close to and too high above the patient. Crowded conditions at the head of the bed in most care settings compound this problem. Unfortunately, the practitioner usually reacts by bending forward at the waist, which serves only to worsen the angle of view. Raise the bed and move it a full 2 feet or more forward if possible. If a lower angle of

view is needed, the practitioner should bend at the knees and not at the waist.

#### Intubation

The paraglossal technique has supplanted older methods of intubation. It is easier to learn, has a higher success rate, and uses the same technique regardless of whether a curved or straight blade is used. I have nicknamed the method the "Diamond Technique," based on the four "Ds" of the steps used to intubate:

- Dental—Always hold the laryngoscope in the left hand. Place the flange of the blade against the right molars with no tongue intervening.
- Deep—Sweep the tongue centrally and insert the blade to the hilt or until resistance is met in the esophagus. If the patient is in the sniffing position, this is usually easy. If the patient cannot be moved safely into the sniffing position, follow the contour

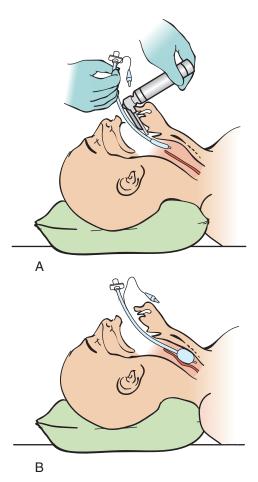

**Figure 213-5** Proper head position is important for successful endotracheal intubation. Axes of the mouth, pharynx, and larynx need to be aligned. **A,** Divergent axes. **B,** Axes in line, or "sniffing position."

of the base of the tongue to reach the esophagus. Place the blade deeply and in the esophagus on purpose. In this position, the location of the tip of the blade is known and, more important, so is the location of the airway: shallow and superior to the blade tip.

- Direct—Once the blade is in the esophagus, lift the handle upward and forward (see Fig. 213-2), using the same technique as in the older methods of intubation.
- Depart—From this position, withdraw the blade while monitoring the view. Most of the time, there will be a slight sensation of "give" when the blade clears the esophagus, and a good intubating view is obtained.

From this position, the practitioner requests the tube from the cricoid pressure technician. Once received, the practitioner inserts it with the right hand guiding the tip down against the right buccal mucosa to avoid obstructing the intubating view (Fig. 213-6). A common mistake is to try to slide the tube straight down the center. This obstructs the view and increases the probability of accidental esophageal intubation. The endotracheal tube is advanced until the tip is at least 2 to 3 cm beyond the vocal cords.

Rarely, the tip of the epiglottis is encountered. If this is the case, lift the epiglottis with the blade tip. Using the right hand, after handing the tube back to the technician, replace the pressure on the cricoid cartilage that is being applied by the pressure technician. Manipulate the trachea to obtain a good view (commonly, the cricoid pressure technician will use too much pressure). When a

**Figure 213-6** Insertion of tube with laryngoscope in place. **A,** Insert the tube with the tip initially against the right buccal mucosa so that a clear view of the vocal cords can be maintained at all times. As it advances, watch the tube pass through the cords. **B,** The tube is correctly placed when the tip is 2 to 3 cm beyond the vocal cords.

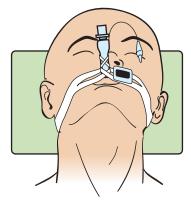

**Figure 213-7** Auscultation points for confirmation of placement are over the stomach (should be lack of sound) and the axillae. The same locations should be used to auscultate in the adult.

good view is obtained, have the cricoid pressure technician replace the same amount of pressure to maintain a constant view. The technician then hands the endotracheal tube back to the practitioner, who intubates the trachea as described previously. The tube insertion depth can be approximated by the Chula formula: 4 cm + (patient height in inches/4). In most patients, this will be between 21 to 23 cm. Inflate the balloon according to manufacturer directions. Most balloons take 10 mL of air.

#### **Confirm Placement**

Listen at the stomach to assess for an esophageal intubation, and then listen in each axilla to assess for equal breath sounds. Listening over the anterior chest is not as accurate as listening in the axillae for determining proper tube placement (Fig. 213-7). Asymmetric breath sounds suggests that the mainstem bronchus was intubated—typically, the right mainstem bronchus because it is more vertical than the left mainstem bronchus.

Next, use a secondary device to ensure proper placement. The devices available include bulb-type and syringe-type esophageal detector devices or carbon dioxide colorimetric devices. These devices are attached to the endotracheal tube after intubation. The bulb device is squeezed shut before being placed on the tube. If the bulb reinflates, the tube is in the proper location. One way to remember this is "reinflate means you're great." If a syringe device is used, aspiration of more than 30 mL of air indicates proper tube placement. Colorimetric devices, which change from yellow to purple with an elevated carbon dioxide level, are also useful. These end-tidal carbon dioxide detectors are placed between the tube and the bag-valve device after intubation: the detectors will change from purple to yellow if the tube is in the proper location. An easy way to remember the colors is "yellow, yellow in the bellow." Carbon dioxide capnographic devices should show adequate respiratory waveforms. These forms are characterized by three phases: baseline, rapid upstroke, and long alveolar plateau, similar to a small "r" written in longhand.

**Figure 213-8** Secure the tube to minimize patient discomfort while maintaining correct positioning. Consider a bite block.

#### Secure

Secure the tube with umbilical tape or a commercial device made for that purpose (Fig. 213-8). Avoid using tape or tincture of benzoin on the face because facial irritation can cause at least temporary skin changes. Consider inserting a bite block if the patient might bite the tube. Insert a nasogastric or orogastric tube. Use chemical restraints with appropriate monitoring to prevent tube removal. Finally, take a chest radiograph to ensure proper depth and placement. The ideal location is to have the tube 2 to 3 cm above the carina.

#### **Rapid-Sequence Intubation**

Rapid-sequence intubation is an important technique to assist intubation in patients who are combative. It prevents laryngospasm and can have other therapeutic benefits. The prime candidate has been the "can't intubate, can't ventilate patient," but in actual practice this is rare. Airway assessment before the procedure should detect patients at risk for this problem, and often alternative methods can be used. Rarely, this may occur without warning, so an intermediate airway, such as a LMA or Combitube, as well as a cricothyroidotomy kit, needs to be readily available. There are many medications from which to choose and the topic can be complex. Here, only the most common technique is explained, and this will be suitable for patients without suspected bronchospasm or increased intracranial pressure.

- Choose the paralytic agent. Succinylcholine 1.5 mg/kg is the first choice unless contraindicated. Contraindications are conditions in which hyperkalemia may be worsened, where there is concern that increased intracranial pressure or intraocular pressure may worsen the patient's condition, or there is a risk of malignant hyperthermia such as the following:
  - End-stage renal disease with missed dialysis
  - Rhabdomyolysis (e.g., patients found down for a long time)
  - Muscular dystrophy of any type
  - History of spinal cord injuries
  - Open globe injury (of controversial significance)
  - Conditions under which there may be increased intracranial pressure
  - History of a recent cerebrovascular accident
  - Burns of greater than 10% body surface area more than 24 hours old but incompletely healed
  - Patients with crush injuries more than 24 hours old
  - Family history of an anesthetic reaction
- If succinylcholine is contraindicated, rocuronium 0.6 to 1 mg/kg is considered by many to be the best alternative. It has a rapid onset of action, but paralysis lasts an average of 50 minutes, placing it second to succinylcholine. However, if succinylcholine is indicated, then a standard dose is 2 mg/kg intravenously. It should not be given until other preparations are made.
- Choose the sedative agent. Etomidate (0.3 mg/kg intravenous perfusion) is the most common choice because of its lack of cardiovascular depression and versatility. Other agents include ketamine 1 to 2 mg/kg in bronchospasm, midazolam 0.2 mg/kg, or thiopental 3 mg/kg in increased intracranial pressure. Each has its benefits and drawbacks, which should be studied before use.
- Choose the adjuncts. Although not indicated in all cases, lidocaine 1.5 mg/kg is considered useful in patients with bronchospasm or concerns for increased intracranial pressure. Atropine should be administered to children younger than 10 years of age at 0.02 mg/kg (minimum 0.1 mg, maximum 1 mg) to inhibit reflex bradycardia before the use of succinylcholine. Atropine should be considered for any adult who is receiving either ketamine or a second dose of succinylcholine during the intubation or reintubation procedure to reduce complications.
- Three minutes before intubation, give adjuncts.
- Two minutes before intubation, give a priming dose (10% of the dose drawn up in the syringe) of succinylcholine (if this medication is to be used for paralysis).

- One minute before intubation, give the paralytic agent (succinylcholine or rocuronium), followed immediately by the sedative (etomidate, midazolam, or thiopental). Begin giving the patient eight vital capacity breaths.
- Assess for adequate paralysis by gently stroking the eyelashes. If there is no response, proceed with intubation as described in previous sections.

#### **NASOTRACHEAL INTUBATION**

Nasotracheal intubation generally requires the patient to be breathing spontaneously, and has the complications of nasal bleeding and sinusitis. It is of limited usefulness except in cases where awake intubation is required. This technique is relatively contraindicated in the combative patient and in those patients with a coagulopathy or bleeding diathesis. It is important to examine the facial anatomy and nares for distortion, trauma, or other contraindications. If no contraindications are noted, use the side with the larger passage. If they are equal, use the right side because this helps reduce trauma from the tube bevel. Use a 6.5-mm tube or smaller, if anatomically indicated.

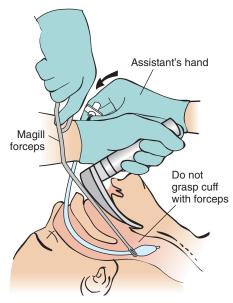

#### **Preparation**

Most nasotracheal intubation failures are the result of inadequate preparation.

- Get an assistant.
- Explain the procedure to the patient. This is the most important step.
- Place the patient in the standard "sniffing" position, as described previously.
- Determine if nasal vasoconstriction is safe. If the patient appears to be at risk for limited perfusion to the nasal area from either local or systemic disease, avoid the use of a vasoconstrictor.
- Prepare the nasopharyngeal path. Place 15 mL of 2% lidocaine with epinephrine (or plain lidocaine, if vasoconstriction is contraindicated) in a Toomey syringe.
- Have one assistant keep the syringe upright to prevent spillage, and connect the Toomey syringe to a small Foley catheter. A red Robinson catheter is preferred.
- While an assistant continues to hold the catheter upright, lubricate the distal catheter with a water-soluble lubricant.
- With the free hand, apply cricoid pressure. This facilitates entry
  of the catheter into the airway. Insert the catheter through the
  nose to the level of the vocal cords. This is approximately twice
  the distance from the front of the lips to the tragus of the ear.
  Ideally, the patient will cough, indicating vocal cord
  stimulation.
- Have the assistant turn the syringe upright and administer about 5 mL of the solution while the patient coughs, which helps disperse the solution.
- Withdraw the catheter, administering another 5 mL of the solution as the catheter is removed.
- Administer the last 5 mL at Kiesselbach's plexus in the anterior nasal passage of the septum. Allow the solution to work while lubricating the endotracheal tube and checking the balloon.

# Two-Handed Nasotracheal Intubation Technique

- Standing at the side of the patient, insert the tube so the leading edge of the bevel is away from the septum. If the left nostril is used, the tube will be initially inserted with most of it positioned above the face and scalp, and then rotated 180 degrees once the turbinates are passed.
- Once the tube is about halfway in, apply cricoid pressure with the nondominant hand. Remember that unlike in training

**Figure 213-9** Nasotracheal intubation using a laryngoscope and Magill forceps. The forceps are not used to pull the tube; rather, they serve to guide the tip of the tube through the vocal cords while an assistant advances the tube. The cuff is frequently damaged if it is grasped. (Modified from Roberts JR, Hedges JR [eds]: Clinical Procedures in Emergency Medicine, 3rd ed. Philadelphia, WB Saunders, 1998.)

models, the trachea is a mobile structure. Use this advantage to move the trachea to assist placing the tube.

- Lean forward and listen for breath sounds through the end of the tube, adjusting both the tube and the trachea to create maximum breath sounds. Once resistance is felt at the vocal cord opening, await inspiration and then guide the tube past the vocal cords. This is often easily felt with the hand manipulating the trachea.
- Pass the tube 26 to 28 cm in an adult, depending on the size of the patient.
- Check and secure the tube in the standard fashion (see Fig. 213-8).
- Direct visualization can also be used for nasotracheal intubation. With the patient supine, use the laryngoscope in the same manner as for standard intubation. While visualizing the cords, use the Magill forceps to grasp the tube already inserted through the nasopharynx and pass it through the cords (Fig. 213-9). Avoid tearing the cuff when grasping the tube with forceps.

#### POSTPROCEDURE PATIENT CARE

- Order daily chest radiographs to verify tube placement.
- The respiratory services department of the hospital usually supplies the ventilator, tape, and other equipment as well as providing care; however, the clinician is ultimately responsible.
- Check the patient and the respiratory setup frequently. Carbon dioxide detectors and whistles can be used to confirm expiratory efforts.

#### **COMPLICATIONS**

- Short-term laryngeal edema: Sore throat occurs in almost every patient after extubation (repeated attempts at intubation by unskilled personnel may cause enough edema to preclude intubation by highly skilled clinicians).
- Trauma
  - Broken teeth
  - Oral lacerations or ulcerations (lip, tongue, pharynx, esophagus, or trachea)

- Bleeding, hematoma, or abscess formation as a result of trauma
- Avulsion of arytenoid cartilage
- Hypoxia resulting from
  - Long duration of procedure
  - Esophageal intubation (most commonly results from not visualizing the vocal cords)
  - Intubation of a bronchus
  - Failure to recognize esophageal or bronchial intubation
  - Pneumothorax
  - Failure to secure the placement
  - Failure to recognize misplacement of the tube
  - Aspiration of vomited material, especially in unconscious or semiconscious patient
  - Laryngospasm
- Hypertension/hypotension
- Bradycardia
- Tachycardia with or without arrhythmias
- Sequelae of long-term endotracheal tube placement
  - Nosocomial infection
  - Pneumothorax
  - Corneal abrasions
  - Epistaxis
  - Sinusitis
  - Vocal cord damage or paralysis (left cord more frequently involved than right)
  - Tracheomalacia and stenosis (occur more frequently in men; are more common with older tubes that use higher cuff pressures)
  - Tracheoesophageal fistula
  - Innominate artery erosion by endotracheal cuff

**NOTE:** Rarely are teeth broken with nasotracheal intubation. However, acute epistaxis and nasal trauma can result. Pulmonary infection can also be caused by nasal flora introduced through the nasotracheal tube.

#### **CPT/BILLING CODE**

31500 Intubation, endotracheal; emergency procedure

#### **ICD-9-CM DIAGNOSTIC CODES**

- 276.2 Acidosis
- 276.3 Alkalosis
- 276.4 Acid-base mixed disorder
- 427.5 Cardiac or cardiorespiratory arrest
- 428.1 Pulmonary edema (left heart failure)
- 491.20 Chronic obstructive bronchitis, without exacerbation
- 491.21 Chronic obstructive bronchitis, with (acute) exacerbation
- 492.8 Emphysema, NOS
- 493.01 Asthma, extrinsic with status asthmaticus
- 493.91 Asthma, unspecified with status asthmaticus
- 518.5 Pulmonary insufficiency following trauma and surgery
- 518.81 Respiratory failure, NOS
- 518.82 Respiratory distress, insufficiency or syndrome; acute
- 518.83 Respiratory failure, chronic
- 780.01 Coma
- 785.50 Shock, unspecified
- 785.51 Shock, cardiogenic
- 785.52 Shock, septic
- 785.59 Shock, hypovolemic or other
- 786.09 Respiratory distress or insufficiency, other, including hypercapnia
- 799.02 Hypoxemia
- 799.1 Respiratory arrest or cardiorespiratory failure

#### **ACKNOWLEDGMENT**

The editors wish to recognize the many contributions by Len Scarpinato, DO, to this chapter in the previous two editions of this text.

### **PERICARDIOCENTESIS**

David James

The normal pericardial space contains 10 to 30 mL of serous fluid, which serves to reduce friction between the surfaces of the visceral and parietal pericardium as the heart moves through the cardiac cycle. An increased amount of fluid in this space may result from a variety of disease processes or trauma. Because of the relatively nondistensible pericardial sac, an increased amount of pericardial fluid may exert pressure on the more compressible myocardium. This in turn may compromise cardiac performance and result in cardiac tamponade. Clinically, this is appreciated by markedly elevated jugular venous pressure (i.e., jugular venous distention), hypotension, and distant heart sounds. Although few patients will have all three of these clinical findings, almost all will have at least one unless they are hypovolemic. The patient may also exhibit restlessness, fatigue, and tachycardia; pulmonary edema may be present with corresponding tachypnea. Estimates of the volume of fluid required to accumulate acutely and produce tamponade range from 60 to 200 mL. A chest radiograph may show a dilated heart, classically in a "water-bottle" shape. Electrocardiographically, pericardial effusions are identified by low voltage in all leads or electrical alternans (i.e., the QRS amplitude or morphology changes on the electrocardiogram [ECG] as the heart swings to and fro within the pericardial fluid). However, electrocardiographic and radiographic signs of cardiac tamponade are often absent. If ultrasonography is available, a fluid echo will be present in the pericardial space. Further ultrasonographic confirmation includes collapse of the right and left ventricular chambers as a result of tamponade (see Chapter 225, Emergency Department, Hospitalist, and Office Ultrasonography [Clinical Ultrasonography]).

Additional findings on physical examination with tamponade include a paradoxical increase in jugular venous distention during inspiration and pulsus paradoxus (a drop in systolic pressure of >10 mm Hg during inspiration). To measure pulsus paradoxus, inflate the blood pressure cuff to greater than systolic pressure. Slowly release the cuff pressure until beats are heard only during expiration, and record this pressure. Keep deflating the cuff pressure until beats are heard continuously during expiration and inspiration, and record this pressure. The difference between these recorded pressures is pulsus paradoxus, as noted by Kussmaul, and is increased because the right ventricle and interventricular septum are forced into the left ventricle by tamponade.

Cardiac tamponade should always be considered as a cause of shock in a medical patient. This includes patients taking oral or parenteral anticoagulants or high-dose steroids, having known cancer or pericardial disease, suspected of having an aortic dissection, or having had a recent myocardial infarction (e.g., ruptured myocardium). In the trauma patient, cardiac tamponade is the most common presentation for a penetrating cardiac injury. It occurs in 80% to 90% of stab wounds and in 20% of gunshot wounds. Tamponade can also be due to iatrogenic causes such as central venous line placement, temporary pacing (transthoracic or transvenous), and cardiopulmonary resuscitation. The causes of effusions, in order of frequency from most to least, include cancer, idiopathic, infectious (including human immunodeficiency virus), postpericar-

diotomy, connective tissue disease, radiation therapy, trauma, and uremia.

Pericardial effusions may be asymptomatic or associated with life-threatening cardiac compromise. The aspiration of pericardial fluid (pericardiocentesis) has diagnostic and possibly therapeutic applications. Pericardiocentesis is an infrequently performed procedure that has the potential for significant patient morbidity and mortality. Optimally, the procedure should be performed in the cardiac catheterization laboratory or intensive care unit, where complete cardiac monitoring and trained support personnel are available. Ideally, the procedure should be performed under real-time ultrasonographic or fluoroscopic guidance to continuously visualize the pericardial fluid. With ultrasonographic or fluoroscopic experience, the clinician should be able to estimate the amount of fluid that can be aspirated and the depth and angle of penetration necessary for pericardiocentesis (see Chapter 225, Emergency Department, Hospitalist, and Office Ultrasonography [Clinical Ultrasonography]).

However, pericardiocentesis may be required under urgent or emergent conditions and in a suboptimal clinical setting if a patient presents with hemodynamic compromise from pericardial tamponade. Patients in whom urgent/emergent pericardiocentesis is contemplated should have intravenous (IV) access and continuous cardiac monitoring. Continuous oximetry, blood pressure monitoring, and supplemental oxygen may also be helpful. If the clinical situation permits, a 12-lead ECG and a chest radiograph should be obtained for review before the procedure (assess for mediastinal shift). Full resuscitation equipment should be readily available.

Before performing pericardiocentesis, the clinician should review the relevant anatomy of the heart, pericardium, and rib cage (Fig. 214-1). It may also be useful to insert a nasogastric tube to decompress the stomach (see Chapter 203, Nasogastric and Nasoenteric Tube Insertion). If time allows, efforts to stabilize the patient with cardiac tamponade include aggressive treatment with IV fluids and parenteral inotropic agents to increase ventricular filling pressures. Preload-reducing agents such as nitrates and diuretics may worsen the patient's condition or even be fatal.

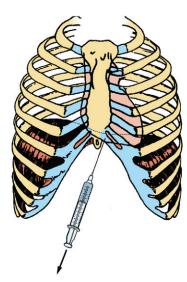

#### **INDICATIONS**

#### **Diagnostic**

Determination of the etiology or confirmation of the presence of an effusion is the diagnostic indicator.

#### **Therapeutic**

The relief of cardiac tamponade (should be performed emergently only if diagnosis is consistent with known prior disease or mechanism of injury or in a resuscitation patient when other causes of electromechanical dissociation have been excluded [e.g., hypovolemia excluded by aggressive fluid replacement, tension pneumothorax excluded by needle thoracostomy]) is the therapeutic indication.

**Figure 214-1** Anatomic relationships of the heart, pericardium, and rib cage. Note the inferior border of the pericardium in relation to the xiphoid process, and the angle the aspirating syringe takes as it enters under the rib cage.

#### **CONTRAINDICATIONS**

- Anticoagulated patient or patient with uncontrolled coagulopathy (relative contraindication in life-threatening situation, absolute contraindication in stable patient).
- Because of the risk of complications, pericardiocentesis should not be performed if a safer alternative exists (e.g., medical management of an effusion).
- In stable patient, pericardiocentesis should not be performed without ultrasonographic or fluoroscopic demonstration of an effusion
- In stable patient, diagnostic pericardiocentesis should be guided by ultrasonography or fluoroscopy in a cardiac catheterization laboratory or intensive care unit.
- In stable patient, pericardiocentesis should not be performed for small, loculated, or posteriorly located effusions.
- In trauma patients, some experts argue that prompt sternotomy should be performed instead of pericardiocentesis; in patients too unstable to make it to the operating room, they argue for an emergency thoracotomy.

#### **EQUIPMENT**

- Pericardiocentesis needle (18-gauge, 4-inch spinal needle with stylet)
- Two 10-mL syringes (Luer type), one with 25-gauge, 2-inch needle
- 50-mL syringe (Luer type)
- 10 mL local anesthetic (e.g., 1% lidocaine)
- ECG machine
- Wire connector with alligator clips (to connect pericardiocentesis needle to ECG lead)
- Basin
- Skin preparation solution (e.g., povidone-iodine, chlorhexidine)
- Sterile towels
- Mask, sterile gloves, eye protection, possibly sterile gown
- Kelly clamp
- Cardiac monitoring equipment, pulse oximetry, supplemental oxygen, automatic blood pressure cuff
- Nasogastric tube
- Access to chest radiography

- Bedside ultrasonography machine or fluoroscopy (in emergent situations, optional but desirable)
- Cook 8-Fr Fuhrman pericardiocentesis catheter kit (usually a soft, multihole catheter; in an emergency, a single-lumen, 6- to 10-Fr central venous catheter can be used), no. 11 blade scalpel, nylon suture (if inserting a catheter for continuous drainage)

#### PREPROCEDURE PATIENT EDUCATION

If the clinical situation allows, describe the procedure to the patient or representative and obtain informed consent. Explain that there will be some discomfort involved, but that removal of even a small amount of pericardial fluid may make an enormous improvement in the patient's clinical status. The alert patient should attempt to remain as still as possible because the needle will be inserted near moving vital organs. If time allows, conscious sedation should be considered.

#### **TECHNIQUE**

- Assemble and connect supplemental oxygen and all cardiac, blood pressure, and oximetry monitoring equipment, and have IV access in place and resuscitation equipment nearby. Some clinicians insert an arterial line for monitoring.
- 2. Place patient in a semirecumbent position (Fig. 214-2) at about 30 to 45 degrees. This position allows the myocardium to "fall back" slightly within the pericardial sac and lessens the likelihood of puncturing the myocardium. The supine position is an acceptable alternative.
- 3. Hook up limb leads of ECG machine and attach one end of connector to lead  $V_{\rm l}.$
- 4. Prepare skin of epigastrium, xiphoid area, and lower chest. Drape with towels to define a sterile field. If time allows, consider using a sterile gown. The clinician should follow universal blood and body fluid precautions when performing this procedure.
- 5. If the patient is awake, anesthetize the subxiphoid area skin with 1% lidocaine solution. (Alternatively, the right or left sternocostal margin near the xiphoid can be used.) Anesthetize the deeper tissue with the 25-gauge, 2-inch needle. Direct the needle under the xiphoid or costal margin toward the left shoulder (alternatively, the suprasternal notch), aspirating continuously. If blood or pericardial fluid returns, withdraw the needle slightly.
- 6. Attach the pericardiocentesis needle to one of the 10-mL syringes and turn the ECG machine on.
- 7. Insert the pericardiocentesis needle through the subxiphoid skin, advancing toward the left shoulder (alternatively, the suprasternal notch), aspirating continuously. Remove the stylet, attach the other end of the ECG connector to the pericardiocentesis needle close to the hub, and then advance the needle 4 to 5 cm

Figure 214-2 Patient lying in semirecumbent position.

while applying negative pressure to the syringe. This may be guided by ultrasonography or fluoroscopy, if equipment is available. Continue advancing the pericardiocentesis needle until blood or pericardial fluid is aspirated, cardiac pulsations are felt, or the ECG shows (a) increased P-wave amplitude, (b) ST segment elevation (i.e., current of injury), or (c) ectopic beats. All of these ECG findings are suggestive of penetration of the epicardium and require withdrawal of the needle slightly, in 1- to 2-mm increments, until the findings disappear.

**NOTE:** To minimize the risk of damaging vital organs, never rock or redirect the pericardiocentesis needle without withdrawing it almost completely (to just below the skin).

- 8. The clinician will often feel the needle give or a "pop" as it enters the pericardium. (The awake patient often complains of chest pain when the pericardium is entered.) Once blood or pericardial fluid begins to flow into the syringe, attach the Kelly clamp to the needle where it penetrates the skin. This will limit any further unwanted travel of the needle.
- 9. Remove the 10-mL syringe, attach the 50-mL syringe to the needle hub, and aspirate the desired amount of fluid. The fluid may be discarded into the basin or sterile containers if laboratory analysis is required. If the blood or pericardial fluid withdrawn clots, it is probably fresh blood from a cardiac chamber. Withdraw the needle slightly and aspirate again. Pericardial fluid may be bloody, but it should not clot.

#### **Blind Insertion Technique**

1. In an emergency, pericardiocentesis may have to be performed blindly (usually because connectors are not available to attach

- the ECG lead to the pericardiocentesis needle). In that situation, a 12-lead ECG machine should still be running continuously with the leads placed in the standard locations.
- 2. Follow previous steps 1 through 6, as much as possible. Next, insert the pericardiocentesis needle through the subxiphoid skin, advancing toward the left shoulder (alternatively, the suprasternal notch), aspirating continuously. Advance the spinal needle until blood or pericardial fluid is aspirated, cardiac pulsations are felt, or the 12-lead ECG shows (a) ST segment elevation (i.e., current of injury), or (b) ectopic beats. Again, these ECG findings are suggestive of penetration of the epicardium and require withdrawal of the needle slightly, in 1- to 2-mm increments, until the findings disappear.

# Placing a Fuhrman Pericardial Drainage Catheter (Seldinger Technique)

Recurrence of an effusion is common; placing a pericardial catheter can minimize the risk of recurrence and decrease the risk of complications with repeat needlesticks.

- Follow previous steps 1 through 8. Then, remove the 10-mL syringe from needle hub, grasp the needle firmly, and pass the guidewire through the needle into the pericardial space (Fig. 214-3). Advance the guidewire until approximately one third of its length is within the patient.
- 2. Stabilize the guidewire with one hand and remove the needle while leaving the guidewire in place. Nick the skin where the guidewire enters with a no. 11 blade.
- Slide the dilator over the guidewire and dilate the skin tract. Several passes will be necessary. Slide the dilator off the guidewire and set it aside.

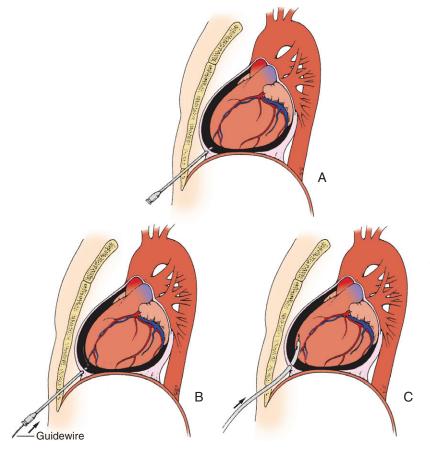

Figure 214-3 A, The needle is first advanced into the pericardial space. B, The syringe is then disconnected from the needle and the flexible guidewire advanced carefully into the pericardial space (best performed under fluoroscopic guidance). C, The needle is withdrawn over the guidewire, the needle tract dilated, and a multihole, soft pigtail catheter advanced into the pericardial space. (From Spodick DH: The technique of pericardiocentesis. | Crit Illin 2:91–96, 1987.)

**NOTE:** The clinician must obtain some assurance that the guidewire is not located in the myocardium; dilating a tract through the myocardium will result in cardiac tamponade or hemorrhage.

- 4. Again, stabilize the guidewire with one hand and with the other thread the 8-Fr pigtail (Fuhrman) catheter over the guidewire. Pass the catheter up through the dilated subcutaneous tract into the pericardium. Advance the entire catheter into the body except for the last 1 inch before the hub. Remove the guidewire and set it aside.
- 5. Suture the pigtail catheter onto the skin, wrapping suture around the catheter between the hub and where it enters the skin.
- 6. Attach and secure the suction device.

#### POSTPROCEDURE PATIENT CARE

- 1. If just a simple aspiration was performed, remove the needle after aspiration is complete and dress the puncture site.
- 2. If a Fuhrman catheter is to be left in place, make sure *both* the catheter and drainage apparatus are secured. They tend to migrate out of the patient if they are not secured.
- 3. Obtain a postprocedure ECG to look for cardiac injury, and a chest radiograph, looking for pneumothorax. Repeat ultrasonography is also advisable to see if fluid remains. Repeat ultrasonography the next day may diagnose a reaccumulation.

Tamponade should be promptly relieved even with a small amount of fluid removed because of the steep pressure–volume relationship of the pericardium. False-negative aspiration rates as high as 80% have been reported with blind or ECG-directed pericardiocentesis. This false-negative aspiration result is often due to clotted blood in the pericardial space that cannot be aspirated or failure to transverse the pericardium. If fluid is removed and relief of tamponade with improvement in hemodynamic status does not occur, consider another diagnosis and arrange transfer of care to the appropriate consultant. Continue to monitor hemodynamic status in the meantime. Other diagnoses may include constrictive pericarditis, lung disease with left ventricular failure, right ventricular infarction, or biventricular failure. Consult a cardiothoracic surgeon if purulent material is expressed with pericardiocentesis.

After diagnostic pericardiocentesis, fluid should be sent for studies similar to those for pleural fluid (e.g., chemical, cytologic, microbiologic analyses). It can be sent for a cell count and differential, glucose, total protein (body fluid/serum ratio), lactate dehydrogenase, pH, appearance (e.g., clear, cloudy), Gram's stain and culture, acid-fast bacillus stain and culture, fungal culture, and cytology.

#### **COMPLICATIONS**

Complication rates vary from 4% to 40%, with potential complications including myocardial puncture with hemopericardium, laceration of the coronary vessels, bradyarrhythmias and tachyarrhythmias, pneumothorax, hemothorax, air embolism, liver laceration, hemorrhage, hypovolemic hypotension from removing large volumes of fluid (e.g., patients with >1 L pericardial effusions), infection, recurrence (up to 70% using blind technique; reduced to 25% if Fuhrman catheter placed), cardiac arrest, and even death. Death usually occurs as the result of recurrence or occurrence of tamponade, hemorrhage, or dysrhythmias. Few if any deaths have been associated with ultrasonography-guided pericardiocentesis. Overall, the complication rate of ultrasonography-guided pericardiocentesis has been reported to be less than 5%. A less serious complication is vasovagal reaction in the alert patient.

#### **CPT/BILLING CODES**

- 33010 Pericardiocentesis, initial 33011 Pericardiocentesis, subsequent
- 33015 Tube pericardiostomy

#### **ICD-9-CM DIAGNOSTIC CODES**

- 017.9 Pericarditis, tuberculous
- 391.0 Acute rheumatic fever with pericarditis (can include effusion)
- 420.0 Acute pericarditis in diseases classified elsewhere (first, code the underlying disease; e.g., tuberculosis 017.9, chronic uremia 585.9, uremia NOS)
- 420.90 Acute pericarditis, unspecified
- 420.90 Effusion, pericardial (acute)
- 420.99 Pericarditis (acute), pneumococcal, purulent, staphylococcal, streptococcal, suppurative, or pyopericardium
- 423.0 Hemopericardium
- 423.3 Cardiac tamponade (first, code the underlying cause)
- 423.90 Effusion, pericardial

# SWAN-GANZ (PULMONARY ARTERY) CATHETERIZATION

Stuart Forman

For over 30 years the use of the balloon-flotation, flow-directed pulmonary artery (PA) thermodilution (Swan-Ganz) catheter has symbolized modern care of the critically ill patient. However, in the past 10 years several studies have found that the PA catheter does not reduce morbidity or mortality. These studies are summarized in the Cochrane Collaborative paper that states "even though the trials measured numbers of deaths in each group at different points of time, all reported that there were no differences between patients who did and did not have a PA catheter inserted" (Harvey and colleagues, 2006). Another meta-analysis in the *Journal of the American Medical Association* similarly showed that "the use of PA catheter neither increased overall mortality in the hospital nor conferred benefit" (Shah and colleagues, 2005).

Alternatively, early goal-directed therapy (EGDT, which uses a regular central line and monitors central venous pressure [CVP] and central venous oxygen saturation [SCVO<sub>2</sub>]) in patients with septic shock demonstrated impressive survival rates in a landmark study in 2001 (Rivers and colleagues, 2001). The standard therapy group had an in-hospital mortality rate of 46.5%, compared with 30.5% for those assigned to EGDT. Protocol patients were resuscitated to a CVP of 8 to 12 mm Hg and a mean arterial pressure of 65 mm Hg. If at this point their SCVO2 was below 70%, packed red cells were transfused to a hematocrit of 30% and dobutamine added, if necessary, until their  $SCVO_2$  normalized to 70%. If still not there, mean arterial pressure was titrated to 65 mm Hg with either norepinephrine or dopamine (Rivers and colleagues, 2001). Subsequent trials have validated these results with similar or better findings (Otero and colleagues, 2006). As a result, many intensive care units have moved away from the PA catheter and are using less invasive methods such as central lines for CVP monitoring and echocardiograms to evaluate cardiac function (see Chapter 90, Echocardiography, and Chapter 225, Emergency Department, Hospitalist, and Office Ultrasonography [Clinical Ultrasonography]). There is even exciting new technology available that provides continuous measurement of cardiac output using just a radial arterial line. That said, PA catheters still have a major role in critical care. Pinsky and Vincent (2005) proposed an algorithm for use of PA catheters (Fig. 215-1); their criteria for initiation of the protocol "would be ongoing circulatory shock despite initial fluid resuscitation efforts or, in the setting of normotension, persistent tachycardia, metabolic acidosis, lactic acidosis, altered mental status, or decreased urine output, since all these are signs or indirect markers of inadequate tissue perfusion." Further study is needed to compare PA catheter-derived outcomes with those using a mere central line. As of this writing, PA catheters still remain an important, although less frequently used, assessment tool in critical care.

This chapter was written for the primary care clinician preparing to insert a PA catheter. All PA catheters generate data such as cardiac output, pulmonary artery wedge pressure, systemic vascular

resistance, and stroke work index; therefore, clinicians using PA catheters should be capable of interpreting and acting on these and other results. Many PA catheters are capable of continuously monitoring cardiac output and mixed venous oxygen saturation (SVO<sub>2</sub>). Further specialized catheters often provide a port or built-in electrode for pacing, four lumens, or the ability to gather specific data regarding right ventricular function. These specialized catheters are beyond the scope of this chapter.

Although many clinicians are proficient with similar procedures and may have cross-over skills, beginners should first observe PA catheter placement several times. Attempts to place the first few catheters should be supervised by a trained, skilled, and experienced clinician. After the clinician gains mastery of the skill of insertion, further study and use of the catheter should increase his or her skills, interest, knowledge, and abilities in the maintenance of a PA catheter as well as in obtaining data. Attending courses devoted to the technology will further enhance proficiency, especially for the subtler applications.

#### **INDICATIONS**

- Refractory acute respiratory distress syndrome (ARDS) or pulmonary edema, especially in patients with renal failure
- Severe hypoxemia requiring high levels (>10 cm) of positive end-expiratory pressure (PEEP)
- Presence of hemodynamic deterioration due to a mechanical complication (e.g., differentiate between mitral regurgitation and acute ventricular septal defect)
- Evaluation of left ventricular function if echocardiogram not available
- Suspected right ventricular dysfunction or infarction
- Preoperative optimization of extremely high-risk surgical patients
- Oxygen delivery and consumption assessment
- The evaluation of and drug titration for severe pulmonary hypertension

#### **Monitoring**

- Titration of drugs or other interventions in a highly unstable patient (e.g., vasodilators, inotropes, pacemaker)
- Refractory heart failure
- Hemodynamically unstable patient unresponsive to conventional therapy
- Unstable myocardial infarction with severely decompensated heart failure
- Right-sided heart failure resulting from severe obstructive lung disease, ARDS, or pulmonary embolism
- Refractory sepsis

#### Resuscitate to a mean arterial pressure of >65 mm Hg

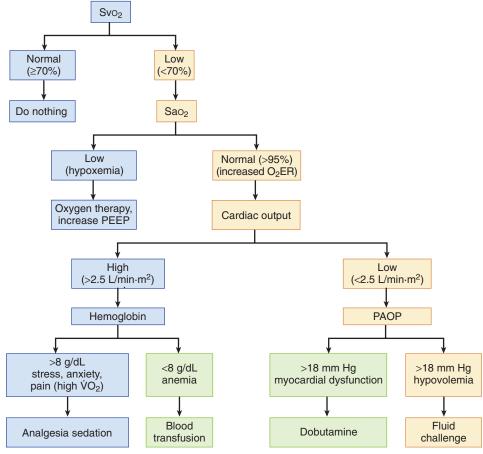

Figure 215-1 Diagnostic and therapeutic algorithm based on mixed venous oxygen saturation (SVO<sub>2</sub>) measurements: therapeutic options to be considered are presented in the rectangles. SaO<sub>2</sub>, arterial oxygen saturation; O<sub>2</sub>ER, oxygen extraction ratio; PEEP, positive end-expiratory pressure; PAOP, pulmonary artery occlusion pressure;  $VO_2$ , oxygen consumption. (From Pinsky MR, Vincent JL: Let us use the pulmonary artery catheter correctly and only when we need it. Crit Care Med 33:1119-1122, 2005.)

 Fluid management in certain complex situations (e.g., shock, postoperative state, ARDS, acute renal failure, intraoperative)

#### **Therapeutic**

- Pacing
- Aspiration of air emboli during seated neurosurgery

#### **CONTRAINDICATIONS**

Contraindications are the same as those for central venous catheterization (see Chapter 211, Central Venous Catheter Insertion), plus the following *relative* contraindications:

- Diagnostic information could be provided by less invasive means (e.g., echocardiography, a therapeutic trial of fluid administration in the hypovolemic patient)
- Prosthetic right heart valve
- Cardiac-paced patient (temporary, internal, or permanent)\*
- Severe hypotension
- Known pulmonary hypertension

- Highly unstable arrhythmias (especially ventricular)
- Right-sided endocarditis or mural thrombus
- Highly unstable respiratory status
- Lack of nursing staff or clinicians trained in use of PA catheters
- Lack of a compatible pressure monitoring apparatus
- Allergy to any component of the catheter (e.g., latex)

**NOTE:** If the underlying relative contraindication can be altered, catheterization may be worth the risk if there are no alternatives.

#### **EQUIPMENT**

- Central venous access with an 8.5-Fr percutaneous sheath introducer kit (see Chapter 211, Central Venous Catheter Insertion)
- Radiopaque PA catheter (7 to 7.5 Fr for adults; Fig. 215-2) with syringe for balloon inflation, occlusive caps for each port, and catheter protective shield

**NOTE:** Standard thermodilation catheters now usually have four lumens. The distal lumen at the tip measures PA and PA occlusion pressures, and is used for blood sampling. A more proximal

of complete bundle branch block is low; however, it may be prudent to use fluoroscopy when placing a PA catheter in a patient with an LBBB. A transvenous or transcutaneous pacer or a PA catheter with pacing capabilities should be available.

<sup>\*</sup>Left bundle branch block (LBBB) was previously a contraindication because of the frequent occurrence of natural or induced right bundle branch block (RBBB) during passage of a PA catheter. This could cause complete heart block (i.e., RBBB + LBBB = complete heart block). A chronic indwelling catheter may also increase the risk of RBBB. Evidence suggests that the risk

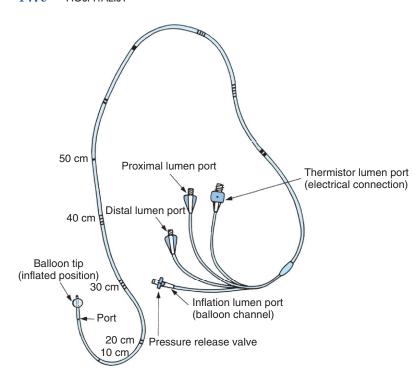

Figure 215-2 Balloon-tipped thermodilution catheter.

lumen (injectate) is used for injecting a thermal bolus for cardiac output measurement (if your Swan-Ganz catheter does not have continuous cardiac output capability). The third lumen is a proximal infusion port for medications; this port may also be used for a thermistor (electrical connection). A fourth lumen is used to inflate the balloon. There may be additional proximal lumens with ports. Catheters coated with chlorhexidine or heparin are also available to reduce the risk of infection and thrombosis, respectively.

- Pressure transducer and monitor (Fig. 215-3)
- High-pressure tubing, connectors, and two three-way stopcocks

- Heparinized saline flush system
- Povidone-iodine solution
- Sterile gowns, drapes, gloves, masks, and goggles
- Surgeon's cap
- Guidewire if changing central line to an introducer sheath (make sure it is the correct diameter and long enough to properly fit through both catheters)
- Suture and sterile dressing for site
- Supplemental oxygen
- Continuous pulse oximetry, cardiac, and blood pressure monitoring
- Fully stocked code cart and defibrillator nearby

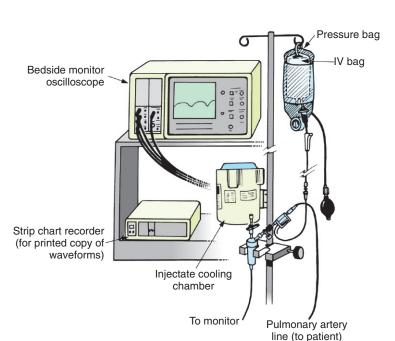

Figure 215-3 Pulmonary artery catheter setup.

#### PREPROCEDURE PATIENT PREPARATION

Because PA catheterization is usually an emergency procedure, written informed consent cannot always be obtained. However, explain the indications, risks, benefits, and any available alternatives to the patient and the family, if possible. If the consent is implied, it should be documented. If time allows, the patient or family should sign for informed consent. Venous access may be established by the procedure outlined in Chapter 211, Central Venous Catheter Insertion. As delineated in Chapter 216, Temporary Pacing, catheterization of the right internal jugular vein provides the most direct access to the right atrium and ventricle, but its use may restrict patient mobility. The broad curve of the left subclavian vein may make it more difficult to traverse than the right internal jugular, but it is a reasonable second choice. The left internal jugular and right subclavian veins are acceptable alternatives. The femoral vein is another option, but it is infrequently used and often necessitates the use of fluoroscopy to properly advance the catheter. The external jugular, axillary, and basilic veins are additional options, but are also often difficult to traverse.

#### **TECHNIQUE**

#### **Before Insertion and General Guidelines**

- 1. Supplemental oxygen should be supplied. If the patient is on a ventilator, the ventilatory settings and alarms should be checked. The endotracheal tube should be secured and suctioned.
- Before the heart undergoes invasive monitoring or an area of the heart is traversed for any reason, record a baseline electrocardiogram (ECG).
- 3. A "time out" should be taken before this (and any) procedure to make sure you have the right procedure, site, and patient.
- Because this procedure may induce arrhythmias, an additional, separate intravenous access site should be available. The introducer sheath has a separate intravenous access site if no other access is available.
- 5. To prevent the loss of a guidewire in a patient, *never* let go of the guidewire during catheter manipulation.
- 6. Observe strict sterile technique. Scrub after donning hair cover, goggles or eye protection, mask, and gown; wear sterile gloves and maintain sterile technique throughout the procedure. Optimally, the entire neck and clavicular area are prepared with povidone—iodine if the internal jugular or subclavian routes are to be used; a similarly sized area should be prepared if another route is to be used. Drape as large of an area as possible, including the majority of the patient and the bed. A three-quarter sheet works well for this purpose. Follow universal blood and body fluid precautions.

#### Conversion to a Sheath or an Introducer

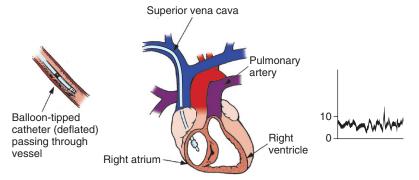

If the venous catheter in place is a multilumen catheter or the single-lumen sheath is not large enough to accept the PA catheter, it must be converted. Use an 8.5-Fr introducer sheath for a 7- or 7.5-Fr PA catheter.

- 1. Insert a guidewire of proper diameter and sufficient length through the existing venous access line. Always maintain control of the guidewire. (Letting go could allow it to slip into the vein and embolize.) Carefully remove the existing venous access line (catheter or sheath) over the guidewire.
- 2. Leaving the guidewire in place, advance the dilator over the guidewire and into the vein to enlarge the lumen. A nick at the skin may be needed to advance the dilator; using a twisting motion when advancing may also be helpful.
- 3. Leaving the guidewire in place, remove the dilator.
- 4. Now place the dilator through the PA catheter introducer sheath and pass them both, as a unit, over the guidewire and into the

- patient's central circulation. Again, using a twisting motion while advancing the unit may facilitate this part of the procedure.
- Remove the guidewire and the dilator, leaving the introducer sheath in place, and cap the sheath with the special cap that allows for PA catheter placement (usually a diaphragm on it).

#### Insertion of the Pulmonary Artery Catheter

- 1. Have an assistant set up, check, calibrate, and zero the electrical equipment. He or she should also level the transducer (see Fig. 215-3).
- 2. Remove the PA catheter from its sterile packaging. If used, thread the catheter protective sleeve (contamination shield) over the distal end of the catheter. Make sure that the docking mechanism is facing the correct direction. It should be able to be connected to the introducer sheath that was inserted earlier. Slide the protective sleeve up the PA catheter, far away from the tip, to keep it out of the way of the tip. Flush the catheter by injecting sterile heparinized saline into the three open ports of the catheter. Make sure that all ports are patent.
- Next, test the balloon before insertion. Attach the smaller syringe to the balloon port and fill the balloon with air. A built-in safety mechanism in the syringe prevents overdistention of the balloon. Allow the balloon to deflate. (Never forcibly deflate the balloon.)
- 4. Hand the proximal end of the catheter to the assistant. Three-way stopcocks should be attached to the three lumens. Have the assistant connect the PA catheter to pressure tubing after internally flushing it with sterile saline.
- Hook up the distal port to the PA transducer and jiggle the end of the catheter. You should see corresponding jiggling on the computer screen. If you do not, have your assistant check the connections.
- 6. Mark the patient's lateral midchest with an indelible ink spot so that the equipment can be lined up horizontally; this spot is considered the zero point. Record this height and the height of the bed mattress from the floor. The strict recording of heights is necessary because a change in height of 1 inch corresponds to a 1.8–mm Hg change in monitored pressure. An assistant or nurse will usually do this.
- 7. If using the right internal jugular approach, direct the catheter toward the superior vena cava. If using the right subclavian approach, aim the curve of the catheter so that it is pointing down clockwise toward the superior vena cava.
  - **EDITOR'S NOTE:** The distance from the right internal jugular vein to the corresponding landmarks is about 5 cm more than when using the right subclavian vein approach.
- 8. ECG monitoring should be continuous throughout the procedure. Pass the deflated balloon-tipped catheter through diaphragm on the protective sleeve and then the sheath to the 20-cm mark; it is marked in 10-cm increments. Watch these distance markings carefully.
- 9. Watch the waveform monitor for a characteristic central venous tracing or a right atrial tracing. The normal range of pressure for the right atrium should be from 0 to 10 mm Hg and the monitor should show respiratory variation. An assistant should monitor the heart rhythm and record these pressures (Fig. 215-4). Three positive deflections can be seen if the scale is enlarged enough on the monitor: the a, c, and v waves.
- 10. Verify that the appropriate scale was picked on the monitor. If the patient is asked to cough, there should be an abrupt increase in the pressure tracing correlating with the abrupt increase in intrathoracic pressure.
- 11. After passing to 20 cm (out of the introducer sheath), rotate the entire catheter 180 degrees so the catheter tip is now pointing up (although you cannot see it) and counterclockwise,

**Figure 215-4** Balloon-tipped catheter passing through vessel to the 10- to 15-cm mark. If passed through internal jugular or subclavian vein, it enters right atrium at 15- to 20-cm mark. Note pressure.

matching the curve of the passage through the heart (see Fig. 215-4).

12. Using the syringe provided with the kit, inflate the balloon with air to the recommended full volume as indicated on the package or the syringe (0.8 to 1.5 mL of air). To avoid vessel damage, never advance the catheter beyond this point without an inflated balloon. The provided syringe is designed to prevent the entry of undesired air. As long as it is not overdistended, the balloon will typically provide a buffer around the distal hard tip of the catheter. Avoid overfilling the balloon! It can burst with dire consequences. Never force air into a PA catheter (Fig. 215-5).

**EDITOR'S NOTE:** Once out of the introducer sheath, never advance the PA catheter without the balloon being inflated. Never withdraw the PA catheter without the balloon being deflated.

13. Pass the catheter to the 30- or 40-cm mark in a quick but not too rapid fashion. While passing the catheter, watch the pressure monitor for the characteristic right ventricular tracing. This tracing looks like a large square root sign without a dicrotic notch. A dramatic rise in the systolic pressure should occur

- during this manipulation (Fig. 215-6A). Record the right ventricular pressures. Also watch the ECG monitor for any ectopy at this stage.
- 14. After confirming its presence in the right ventricle, pass the catheter without delay to the 40- to 50-cm mark, into the PA. The PA will have the same systolic pressures as the right ventricle but the diastolic pressures will be higher. You will see a dicrotic notch on the downhill distal side of the triangles (Fig. 215-6B). Record the pressures. Normal PA pressures are 15 to 25 mm Hg systolic and 8 to 16 mm Hg diastolic, with a mean of 10 to 20 mm Hg.
- 15. Once in the PA, continue passing the catheter at a much slower pace, watching for the characteristic pulmonary capillary wedge pressure (PCWP) tracing at about the 50-cm mark on the catheter (Fig. 215-6C). With PCWP tracings, the systolic pressure is lost and you are left with the "wedge pressure." In fact, the PA diastolic pressure is a good estimate of the wedge pressure if for some reason you cannot get a wedge pressure. This is the place where the vessel has become occluded and the catheter no longer reads PA pressures; rather, it reads pressure reflected back from the left atrium through the capillaries. If the patient has a normal mitral valve, the PCWP approximates the left

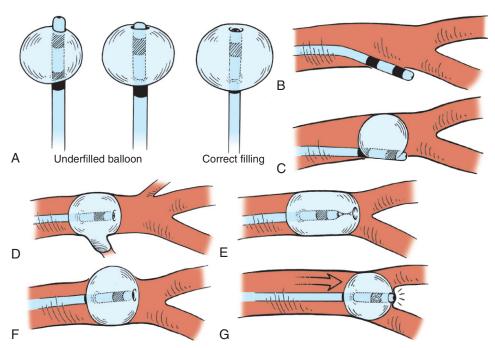

Figure 215-5 Correct filling of the balloon and possible complications. **A,** Underfilled and correct filling. **B,** Tip perforates wall of vessel when balloon is not inflated. **C,** Eccentric balloon (inaccurate wedge) with risk of wall rupture. **D,** Overfilled balloon inadvertently distending down side vessel. **E,** Inaccurate and overdistention of balloon can cause catheter tip occlusion. **F,** Overwedge (see Troubleshooting section). **G,** Underinflated catheter with protruding tip.

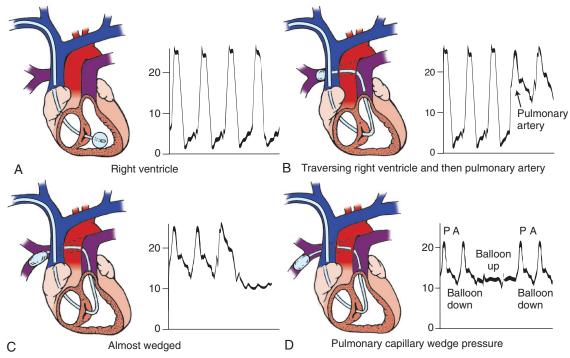

Figure 215-6 Tracings recorded through the catheter as it traverses the right ventricle and pulmonary artery and is wedged: the right ventricle (A), the pulmonary artery (B), almost wedged (C), and, finally, the wedged position (D).

ventricular diastolic pressure (Fig. 215-6D). In the absence of elevated end-expiratory pressures or obstruction of the pulmonary veins, PCWP approximates left atrial mean pressure to within 2 mm Hg. If desired, using the Starling pressure—volume relationships, left ventricular end-diastolic volume can also be estimated.

- 16. Once the balloon is wedged, allow it to passively deflate and watch for the phasic PA tracing. Do not aspirate to deflate the balloon; active deflation may cause rupture.
- 17. Inflate the balloon again and allow it to deflate to observe the two different tracings. If the syringe and balloon were designed to hold 1.5 mL, this should be the amount required to wedge the catheter safely. If any less accomplishes it, the catheter's location is too distal; withdraw it until 1.5 mL wedges it. If 1.5 mL does not wedge the balloon, pass the catheter further. Although the PCWP is called an occlusion pressure, the inflated balloon actually floats distally and then occludes the vessel. The vessel is not occluded from inflation at a fixed location. The catheter should be placed at the most proximal point where a wedge pressure is observed. If you deflate the balloon and do not see the PA pressures, either the balloon did not truly deflate, or you have a "permanent wedge." If the latter is the case, you must withdraw the catheter until you see PA pressures again and then refloat the catheter.
- 18. The wedge pressure should be read at end expiration and recorded.
- 19. Extend the catheter protective sleeve, if used, and attach it to the sheath with the docking mechanism.
- 20. Secure the entire assembly with suture and adequate tape. Apply a sterile dressing.
- 21. Order a chest radiograph and auscultate the chest bilaterally to exclude a pneumothorax.
- 22. Begin infusion of necessary fluids or medications.
- 23. If the patient was moved, the assistant should rezero the equipment.
- Document the procedure in the chart, including the tracings, and record end-expiratory values. Additional documented

values should include the PA pressure, the PCWP, and the cardiac output (performed by the assistant and not detailed here).

#### **Confirmation of Proper Placement**

- 1. Obstruction is excluded by the ability to flush the catheter before inflating the balloon.
- When the balloon is inflated, the typical PA tracing disappears. It reappears promptly after the balloon deflates.
- 3. PCWP is lower than or equal to PA diastolic pressure.

#### **TROUBLESHOOTING**

It is common to get salvos of premature ventricular contractions as the catheter passes through the right ventricle. Usually this problem will resolve with passage of the catheter to the pulmonary artery. If the ectopy does not resolve, the balloon must be deflated and the catheter brought back to the superior vena cava. The catheter may also be coiling in the right ventricle. If further attempts to pass it are unsuccessful, administer an intravenous bolus of lidocaine (75 to 100 mg) and attempt passage under fluoroscopy.

If a PÅ or PCWP tracing cannot be obtained, keep the balloon deflated, pull the catheter back to 20 cm, and try inserting again. Consider inserting the catheter using a clockwise twisting action. If this fails, try counterclockwise reinsertion. Having the patient take some deep breaths may also help pass the catheter. Occasionally the tip of the PA catheter gets malpositioned in the chest. If the tip lies above the level of the left atrium (with the patient lying down, this would be anterior), the alveolar pressure may be greater than the pulmonary capillary pressures and you will get an errant reading. Again, fluoroscopy may be helpful here.

Some clinicians recommend injecting cold, sterile saline solution to enhance passage; this may stiffen the catheter, which may have softened because of the warmth of the body. Occasionally, a guidewire and fluoroscopy are necessary to advance the catheter. Repositioning the patient may help.

In patients with a very low ejection fraction, an inotrope may have to be administered to facilitate passage. It may also be difficult to pass a PA catheter in patients with tricuspid regurgitation or pulmonary hypertension. Again, having the patient take deep breaths may facilitate passage in all of these situations.

For a normal-sized adult, from the subclavian or internal jugular site, insertion beyond 50 cm (or 15 cm after entering the right ventricle) predisposes the catheter to coiling, which can lead to knotting.

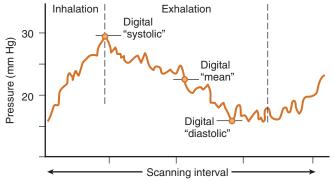

When a catheter's location is too distal in the vessel, a tracing called an *overwedge* may be seen. This is likely to occur when the balloon is not filled with enough air. After allowing the balloon to deflate, withdraw the catheter and attempt to wedge it again, this time with the balloon fully inflated to its correct volume (see Fig. 215-5). Persistent underinflation of the balloon when wedging can damage the pulmonary vessels or the endocardium and may cause arrhythmias, especially if the catheter tip is exposed (see Fig. 215-5A and G). There are several possible mechanisms, such as overinflation or underinflation of the balloon (see Fig. 215-5B, C, F, and G), that could cause rupture of the PA; fortunately, these are unlikely.

When air is present in the catheter damping can occur, which has an opposite effect to that of overwedging. It appears like a regular tracing, but the variations are damped. Air bubbles should be removed from the connecting tubes by aspirating and flushing the catheter. If blood cannot be aspirated, yet the catheter flushes easily, suspect a ball-valve thrombus at the catheter tip. Inject 5000 U of heparin into the lumen and allow 15 to 30 minutes for it to take effect. Initiate a continuous drip of heparin (not to exceed 20,000 U for 24 hours). If still unsuccessful, withdraw the catheter gradually 5 cm at a time, watching for waveforms.

Lesions obstructing the mitral valve, such as mitral stenosis, can interfere with the accuracy of the PCWP as an estimate of left ventricular diastolic pressure. Respirations can also cause significant variations in the pressure readings for the PA catheter. Make calibrated strip chart recordings for all measurements derived from the catheter and then measure again at end expiration (Fig. 215-7). Finally, high PEEP settings on a ventilator can falsely elevate wedge pressures.

#### **COMPLICATIONS**

Possible complications are the same as for central venous catheterization (see Chapter 211, Central Venous Catheter Insertion), *plus* those discussed in the following sections.

**Figure 215-7** Respiratory variation of the pulmonary artery catheter tracing. (From Wiedemann HP, Matthay MA, Matthay RA: Cardiovascular-pulmonary monitoring in the intensive care unit: Part 1. Chest 85:537–549, 1984.)

#### **During Pulmonary Artery Catheter Placement**

- Pulmonary infarction: Can result from leaving the balloon inflated too long.
- Atrial and ventricular ectopy or conduction changes: Advancement into the PA may decrease ectopy. However, withdrawal of the catheter may be necessary. Usually the ectopy is transitory, but if an unstable rhythm persists, medical treatment or electrical conversion may be necessary.
- Knotting of the catheter can occur inside or outside of the heart (more likely with smaller-bore catheters [e.g., 5 Fr]) and, rarely, cause injury to intracardiac structures. Inflating the balloon while in the subclavian vein or superior vena cava may minimize the risk of knotting. On the contrary, to avoid injury to the pulmonic or tricuspid valve, do not withdraw the catheter with the balloon inflated. Also, if resistance is noted with attempted withdrawal, obtain a chest radiograph to exclude the possibility of knotting or entanglement in the heart. The catheter rarely can get looped around the papillary muscle of the tricuspid valve so that removal is impossible.
- Malposition: The most common malposition occurs when the PA catheter turns up the internal jugular instead of down into the superior vena cava. If, while advancing, you feel resistance, deflate the balloon, do not advance any further, and get a radiograph. If the PA catheter is malpositioned, try to carefully reposition it or use fluoroscopy. Rarely, vessel wall puncture and insertion into undesirable places (e.g., subclavian artery, pleural space) may occur.
- Cardiac perforation and tamponade (extremely rare).

# With Continued Presence of the Pulmonary Artery Catheter in the Central Circulation

- Pulmonary infarction: Leaving the balloon inflated too long or downstream displacement of the deflated balloon (causing "permanent wedge"—described earlier) can block an artery and cause infarction. Infarction can also result from thrombosis.
- Pulmonary hemorrhage: More common in the presence of pulmonary hypertension, possibly associated with the higher pressures forcing the tip through the vessel wall. Cautiously obtain PCWP in patients with pulmonary hypertension. Hemorrhage can also result from pulmonary infarction.
- Mural (or elsewhere) thrombus formation: Thrombosis may develop anywhere throughout the course of the catheter. It can occlude any of the veins through which the catheter has passed (or elsewhere).
- Balloon rupture or catheter fracture: If balloon rupture is suspected, aspirate into the syringe the same gas volume used for inflation, disconnect the syringe, and leave the stopcock open to vent the balloon. Remove the catheter immediately to prevent latex fragments from embolizing.
- Endocarditis: Aseptic vegetations are found on autopsy in approximately 30% of patients who have had a PA catheter. Both aseptic and septic vegetations may be more common in burn patients.
- Sepsis: Frequent manipulations of the catheter, as well as leaving the catheter in place more than 3 days, increase the risk of positive blood cultures. After 24 to 48 hours, if the catheter has become partially withdrawn, advancing the catheter may introduce bacteria from the skin insertion site or the catheter itself. No data show that aseptic protective sleeves prevent this from happening. PA catheters, like any other catheters, should be left in place only as long as necessary.
- Hemoptysis: Can be caused by flushing the catheter when it is in the wedged position.
- Embolism (air or thrombotic).
- Pulmonary artery rupture.

- Pseudoaneurysm.
- Inaccurate diagnosis because of malfunctioning or malpositioned catheter.

#### POSTPROCEDURE CATHETER CARE

- Flush the catheter with heparinized saline every 30 minutes.
- Inflate the balloon only when measuring the PCWP. To avoid pulmonary infarction, leave it inflated for a maximum of 60 seconds only. To exclude the possibility of catheter obstruction before inflation, flush the catheter each time before inflating the balloon. If the catheter is occluded, there is no point in inflating the balloon.
- For obstruction, attempt to reposition the catheter. If a thrombus is suspected, use the same technique as used for clearing a ballvalve thrombus.
- Adjust the position of the catheter as necessary. Otherwise, the catheter may soften and migrate to a more distal site, predisposing to distal or branch vessel occlusion. If the PA pressure tracing shows a loss in phasicity and begins to resemble the PCWP tracing (without balloon inflation), withdraw the catheter until the typical phasic PA tracing reappears. Always deflate when withdrawing to avoid damage to intracardiac structures.
- Remove, inspect, and replace the sterile dressing daily.
- Obtain daily chest radiographs to check for catheter migration and to exclude pulmonary infarction.

# **TEMPORARY PACING**

William Fllert

For various reasons, primary care clinicians may need to perform temporary cardiac pacing. Several types of pacing are available, with the primary purpose being to maintain circulatory stability until either the situation resolves or a permanent pacemaker can be installed. This chapter covers external (transcutaneous) and internal (transvenous) emergency ventricular pacing. Transesophageal pacing, usually limited to atrial pacing, and transmyocardial transthoracic pacing are beyond the scope of this chapter.

The basic uses for temporary cardiac pacing are as a standby should the patient become symptomatic or complete heart block occur and as a way to increase heart rate during periods of symptomatic bradycardia. In addition, overdrive pacing may be used to terminate arrhythmias (e.g., sustained supraventricular or ventricular tachycardia); atrioventricular (AV) sequential pacing may be used to prevent arrhythmias. "Medicinal" pacing (e.g., atropine, isoproterenol) is also available, with advanced cardiac life support (ACLS) guidelines being helpful to guide its use. Overall, the indications for temporary pacing can be divided into therapeutic, prophylactic, and diagnostic categories. For the purposes of this chapter, only therapeutic and prophylactic pacing are covered.

#### **EXTERNAL (TRANSCUTANEOUS) PACING**

Most defibrillator/cardioversion units are now capable of performing external transcutaneous pacing. Modern transcutaneous pacing units represent a major improvement over the units first developed in the 1950s. Those units frequently inflicted severe chest and back muscle stimulation and discomfort, and they often left burns on the skin. At least one suicide was recorded of a pacer-dependent patient who removed the leads from one of the older units to "end the pain." In the 1960s, transcutaneous pacing was largely replaced with the newly available transvenous pacing.

Subsequent discoveries rejuvenated transcutaneous pacing, especially since the 1980s. Researchers found that increasing the pulse duration from 2 to 20 milliseconds (msec) not only increased the safety of transcutaneous pacing (reduced the risk of ventricular fibrillation), but reduced the required current. Reduced current meant less pain and fewer burns. The development of electrodes with a larger surface area also decreased the pain and risk of tissue burn. Use of larger electrodes allows for a reduction in the current density, or the amount of current penetrating per square unit of skin. These developments have resulted in more frequent use of transcutaneous pacing, especially on a standby basis, and consequently decreased the use of transvenous pacing.

One of the shortfalls of external pacing, even with today's somewhat sophisticated equipment, is the difficulty of achieving capture in about one fifth of patients. Reasons for difficult or ineffective external pacing include increased intrathoracic air (such as barrel chests or chronic obstructive pulmonary disease), a large pericardial effusion or tamponade, recent thoracic surgery, obesity, and the improper placement of electrodes. Increased output for capture may be required in these individuals. Another shortfall is that it is rare for patients not to complain of some pectoral muscle stimulation.

Although most patients rate the discomfort as mild or moderate and easily tolerable, approximately one third of patients rate the pain as severe or intolerable. Therefore, analgesics, narcotics, or sedatives should be considered when using the external pacer, especially if the required mean current for capture is 50 milliamperes (mA) or more (a common threshold).

Because the high voltages required for external pacing produce significant muscle twitching, conventional electrocardiographic (ECG) monitors and recorders are useless. To provide decent tracings despite the large pacer spikes and their aftermath, routine ECG monitors must be equipped with an *output adapter*. Fortunately, most external pacer units come equipped with a monitor capable of filtering the spikes. Without an adequate ECG monitor, treatable ventricular fibrillation could be masked by the large pacing spikes, with disastrous results. This is one of the grave risks of transcutaneous pacing.

#### **Indications**

- Short-term pacing until transvenous pacing can be initiated or underlying conditions requiring pacing are corrected (e.g., drug overdose, hyperkalemia)
- When medical therapy is not immediately available, or when significant bradyarrhythmias have not responded to medical therapy (e.g., atropine, isoproterenol)
- Symptomatic patients (e.g., syncope, presyncope, dizziness, fatigue) with type I or type II second-degree AV block, third-degree or complete AV block, asystolic pauses exceeding 3 seconds, or an escape pacemaker rate less than 40 beats per minute (bpm); also for patients who become symptomatic because of a bifascicular block or sinus node dysfunction
- As a standby or prophylaxis in conscious patients with hemodynamically stable bradycardia
- As a standby or prophylaxis before surgery in patients with a preexisting cardiac conduction block (anesthesia can exacerbate the block); also before cardiac diagnostic studies
- As a standby or prophylaxis in conscious patients with an expected bradyarrhythmia or a new type II second-degree, thirddegree, or complete AV heart block in the setting of ischemia or infarction (frequently seen with acute anterior or inferior wall myocardial infarctions or digoxin overdose)

**NOTE:** Preliminary trial of pacing should be performed to ensure that capture is achievable and that pacing is tolerated by the patient.

- In children with primary bradycardia from congenital defects or after open-heart surgery
- To be considered when fluoroscopy (the preferred technique) is not available for transvenous pacer insertion

#### **Contraindications**

All of the contraindications are relative.

- Bradycardia in patient with significant hypothermia; as the core temperature drops, the ventricles become more irritable and prone to fibrillation that is resistant to defibrillation. In addition, bradycardia may be physiologic due to a decreased metabolic rate in these individuals.
- Bradycardia in children: usually due to hypoxia or hypoventilation, the best intervention is to provide an adequate airway as opposed to pacing (exceptions as mentioned in the Indications section).
- Overdrive pacing in tachyarrhythmias with rates greater than 180 bpm because that is the maximal rate of most external pacers.
- Bradyasystolic or asystolic arrest of more than 20 minutes' duration because of the well-documented poor resuscitation rates.
- Patient is unable to cooperate or tolerate the procedure (in lifethreatening situation, provide sedation).
- Lack of therapeutic benefit because of advanced disease or terminal illness.

#### **Equipment**

- Two 8-cm electrodes. These are usually round or rectangular and packaged in pairs. The negative electrode may also be labeled "front," "apex," or "anterior"; the positive electrode may be labeled "back" or "posterior."
- Razor or scissors to remove body hair from the area of electrode placement.
- Pacing unit (contains pulse generator and monitor). The best units allow either fixed-rate or demand mode. Most allow a range from 30 to 180 bpm, with current output from 0 to 200 mA. Pulse durations vary from 20 to 40 msec and are not adjustable by the operator. To protect health care providers, some pacers shut off when an electrode falls off the chest.

**NOTE:** Most defibrillator/cardioversion units contain a transcutaneous pacing unit as an integral part of the system.

 ECG leads capable of monitoring during transcutaneous pacing. If not purchased as part of the pacing or defibrillator/cardioversion system, an output adapter to a separate ECG monitor is required to "blank" or neutralize the large electrical spikes from the pacer.

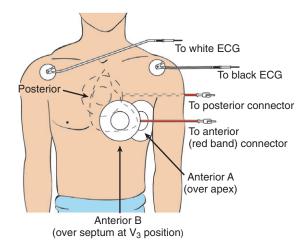

#### **Preprocedure Patient Preparation**

If time allows, explain the purpose and benefits of the procedure as well as the risks of not performing the procedure to the patient or representative. The patient should know what to expect, the sensations he or she may experience (e.g., muscle contractions, a slight tingling, burning or shocking sensation), and that although this may be uncomfortable, the majority of patients tolerate it well. Explain what will be done to minimize the discomfort (e.g., analgesic, sedation). A signed consent is not required to perform this procedure; however, implied consent should be documented in the medical record (e.g., "the risks and benefits have been explained to the patient, who agrees with having the procedure").

Any dirt or debris should be cleaned from the skin; however, avoid using any flammable liquids such as alcohol. Patients with significant body hair may need to be shaved (unconscious patients) or the hair clipped or trimmed (conscious) to ensure good skinelectrode contact. Shaving should be avoided, if possible, in the conscious patient because any nicks or lacerations can increase the discomfort and skin irritation during pacing.

#### **Technique**

1. Attach the exposed adhesive surfaces of two large electrode patches to the anterior and posterior chest walls (Fig. 216-1). The negative (anterior) electrode should be placed over the apex (at the point of maximal impulse) or the septum of the heart (the

**Figure 216-1** External (transcutaneous) pacing. The anterior electrode is placed at the apex (A), which is to the left of the sternum over the point of maximal impulse, or over the septum (B), which is the V<sub>3</sub> position. The posterior electrode is placed to the left of the spinal column on the directly behind the anterior electrode. (Adapted from Dahlberg ST, Benotti JR: Temporary cardiac pacing. In Rippe JM, Irwin RS, Alpert JS, Fink MP [eds]: Intensive Care Medicine, 2nd ed. Boston, Little, Brown, 1991.)

lead  $V_3$  position), and the positive (posterior) electrode directly behind the anterior electrode, to the left of the thoracic spine, between the spine and the left scapula. Alternatively, the positive electrode can be placed on the right upper chest with the negative electrode over the apex of the heart.

- 2. If time allows, prepare the patient with analgesia such as a narcotic or sedation with a benzodiazepine (especially helpful if the required mean current for capture is ≥50 mA).
- 3. Turn on the pacing unit. Set the heart rate (e.g., 80 bpm) to demand pacing. Set the current output and sensing thresholds at levels similar to those used for internal pacing; however, remember that larger outputs are necessary. Keep in mind that for demand pacing, external units often do not have sensing thresholds. The final current output setting is usually 1.25 times the initial capture threshold. Patients with conditions that cause difficult or ineffective pacing may require higher outputs for capture. At these higher outputs, the resultant muscle twitches may be so severe as to preclude external pacer use.
- 4. Apply the electrical stimulation to the electrodes. For conscious patients, slowly increase the output from the minimal setting, at 5- to 10-mA increments, until capture is achieved. Electrical capture is usually indicated by a widening of the QRS complex and especially by a broad T wave. The output required to obtain capture is defined as the pacing threshold. For asystolic or unconscious patients, begin at full output (200 mA) and decrease until capture is achieved, which defines the pacing threshold. The final current output should be set at the pacing threshold or 5 to 10 mA above it. When transcutaneous pacing is used as a standby technique, most clinicians document capture by initiating a brief period of pacing at a rate slightly higher than the patient's intrinsic rate. The pacing output threshold is then recorded and the pacing unit is returned to standby mode.
- 5. When successful pacing is achieved, prophylactic intravenous access (central venous [CV] catheter) through the right internal jugular vein may be helpful in case an internal pacer is needed urgently. Because external pacers have up to a 20% failure rate, having CV access available minimizes the risk of having to obtain it during a "code" situation.
- 6. Monitor continuously for capture and potential complications (e.g., treatable ventricular fibrillation, burns). The only sure sign of electrical capture is the presence of a consistent ST segment and T wave after each pacer spike. Palpation of the carotid to

confirm a pulse is not helpful because the muscle stimulation and contractions produced by the pacer simulate a carotid pulse.

**NOTE:** The increased use of external pacers has surely reduced the number of prophylactic internal pacers placed. However, in non-transient situations, external pacing is always a temporary measure until an internal pacer (probably transvenous, as described in the next section) can be placed.

#### **INTERNAL (TRANSVENOUS) PACING**

Clinicians who may need to insert a transvenous pacemaker should be familiar with the equipment and its use before needing it in an emergent situation. There are usually two lights, a sense indicator light, which is illuminated when a cardiac impulse is sensed, and a pace indicator light, which is illuminated whenever a pacing stimulus is generated. There is also usually a button to test the battery to ensure adequate voltage to operate the pacemaker generator. Although newer models have digital displays and more sophisticated pacing options, they function basically the same as older models.

#### **Indications**

#### Therapeutic

- Symptomatic, hemodynamically compromising or life-threatening bradyarrhythmias unresponsive to pharmacologic therapy (e.g., systolic blood pressure <80 mm Hg, change in mental status, angina, pulmonary edema), including sick sinus syndrome
- Bradycardia with ventricular escape rhythm, unresponsive to pharmacologic therapy

**NOTE:** For tachyarrhythmias of less than 150 bpm, neither immediate cardioversion nor an immediate pacer is necessary.

#### Prophylactic (in Setting of Acute Myocardial Infarction)

- Symptomatic sinus node dysfunction or Mobitz type I seconddegree AV heart block that is not responsive to atropine therapy
- Second-degree Mobitz type II, third-degree, or complete AV heart block\*
- Newly acquired bundle branch block with first-degree AV block
- Bilateral or alternating bundle branch blocks
- An old right bundle branch block with first-degree AV block and a new fascicular block

#### **Contraindications**

Contraindications include those listed in Chapter 211, Central Venous Catheter Insertion, and those listed previously for external pacing. Other contraindications include the following:

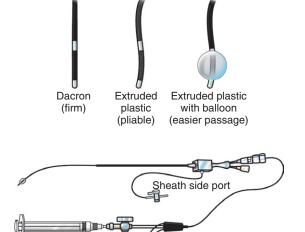

- A situation in which the bradycardia is well tolerated and the symptoms are intermittent, mild, or rare.\*
- Bradycardia in patients with significant hypothermia; as the core temperature drops, the ventricles become more irritable and prone to fibrillation (especially if the pacing wire contacts the heart muscle) that is resistant to defibrillation. In addition, bradycardia may be physiologic because of a decreased metabolic rate in these individuals (relative contraindication).
- Digoxin toxicity and other drug ingestions that may increase the irritability of the myocardium (relative contraindication in lifethreatening situation).

- Presence of a prosthetic tricuspid valve (*relative contraindication* in life-threatening situation).
- Depending on access site, planned neck or clavicle surgical procedures (relative contraindication, may affect choice of site).
- Distortion of local anatomy or landmarks; for insertion from subclavian, moderate to severe chest wall deformities that distort local anatomy (relative contraindication, may affect choice of site).
- Suspected injury to the superior vena cava (*relative contraindication*, may affect choice of site; e.g., superior vena cava syndrome, in which insertion from below the diaphragm is preferable).
- Bleeding diathesis, anticoagulation therapy, or concurrent thrombolysis or fibrinolysis (unless emergent pacing is required, and then antecubital venous cutdown access is preferred).
- Full-thickness burn, cellulitis, or other infection over the anticipated insertion site (*relative contraindication*, may affect choice of site).
- Pneumothorax or hemothorax on the contralateral side or inability to tolerate pneumothorax on the ipsilateral side (*relative contraindication* in life-threatening situation).
- The absence of informed consent (relative contraindication in lifethreatening situation).
- Patient is unable to cooperate or tolerate the procedure (relative contraindication in life-threatening situation, provide sedation).
- Bradyasystolic and asystolic arrest of more than 20 minutes' duration because of the well-documented poor resuscitation rates (relative contraindication).
- Lack of therapeutic benefit because of advanced disease or terminal illness (relative contraindication).
- Suspected prior injury to the vein intended for insertion or vasculitis that predisposes to sclerosis or thrombosis of the veins (relative contraindication in life-threatening situation).
- Previous long-term catheterization, injection of hyperosmotic or irritant solution, or recently discontinued catheter in the same vein (*relative contraindication* in life-threatening situation).
- Contraindications specific to internal jugular vein access include significant carotid artery disease, distorted cervical anatomy, and recent, unsuccessful contralateral cannulation (to prevent bilateral neck hematomas, which could compromise the patient's airway).
- Subclavian insertion during cardiopulmonary resuscitation (CPR). (If CPR can be halted briefly, this may be beneficial; jugular access can usually be obtained without stopping CPR. Otherwise, peripheral access may be preferable.)
- Children (relative contraindication and rarely needed; better intervention is to treat the cause [e.g., hypoxia]. If pacing is needed, the internal jugular vein is the best access route.)
- Patients receiving ventilatory support with high end-expiratory pressures (e.g., positive end-expiratory pressure; relative contraindication in life-threatening situation; if possible, ventilation should be interrupted briefly while attempting to cannulate the vein for access).
- Patients with morbid obesity, marked cachexia, or severe hypovolemia may be better served by using common femoral or peripheral vein access.
- Severe hypovolemia (relative contraindication due to difficulty in insertion).

#### Equipment

• Bipolar transvenous pacing catheters (Fig. 216-2), 4 to 6 Fr, may be soft and pliable and made from extruded plastic or firm, relatively nonpliable, and made from woven Dacron. Some practitioners prefer soft, flexible, semifloating catheters; however, these are more difficult to maneuver and less stable once positioned. Flow-directed, flexible, balloon-tipped pacing catheters are also available. They are similar to balloon-tipped pulmonary artery catheters, but without an open lumen (see Fig. 216-2). Stiffer catheters are usually easier to maneuver than balloon-tipped

<sup>\*</sup>In patients with an inferior myocardial infarction, relatively asymptomatic second- or third-degree heart block can occur. Pacing in such patients should be reserved for symptoms or the presence of a deteriorating bradycardia. If not paced, patients should be monitored closely with a pacer nearby or on standby. It should have been tested for capture and patient tolerance.

**Figure 216-2 A,** Distal tips of transvenous pacers. **B,** Transvenous balloon-tipped temporary pacer.

catheters; however, balloon-tipped catheters are easier to insert without fluoroscopy. There is also always the option of using a balloon-tipped, pacer-equipped pulmonary artery catheter (Swan-Ganz). One prospective, randomized trial (Ferguson and colleagues, 1997) demonstrated that balloon-flotation pacing wires are easier to insert, quicker to position, and more likely to be optimally positioned than semirigid electrode wires.

- Unipolar electrode catheters are available; however, unipolar catheters must rely on a second, external electrode to be placed on the skin. This electrode is very susceptible to any external electrical interference; therefore, bipolar catheters are preferred.
- A flexible "J"-shaped catheter is available specifically for temporary atrial pacing.
- Availability of fluoroscopy is ideal.

Syringe (for balloon inflation)

- Pacer pulse generator (Fig. 216-3) with a new or spare battery.
- Extension cable and alligator clips to connect pacer to catheter.
- ECG monitoring capability during insertion.
- Venous insertion site.
- Gauze squares.
- 3-0 nylon suture.
- Advanced cardiac life support equipment (defibrillator, airway management equipment, resuscitative drugs).

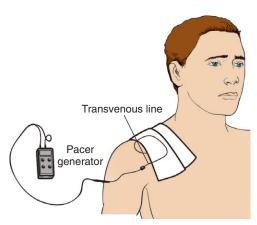

Figure 216-3 Transvenous line and pacer in place.

#### **Preprocedure Patient Preparation**

See Chapter 211, Central Venous Catheter Insertion.

If possible, obtain written informed consent. The conscious patient should know what to expect, the sensations he or she may experience (e.g., possibly being covered by a drape, needlesticks while obtaining central access), and that although this may be uncomfortable, everything possible will be done to minimize the discomfort (e.g., local anesthetic). In many cases, pacing is an emergency procedure and written informed consent cannot be obtained. However, after the patient is stabilized, the situation, risks, and benefits should be explained to the patient or representative. Implied consent should be documented in the medical record (e.g., in the conscious patient: "the risks and benefits have been explained to the patient, who agrees with having the procedure"). Always outline the complications of either performing or withholding the procedure.

#### **Technique**

All steps should be performed using aseptic technique and following universal blood and body fluid precautions. Venous access is established by the procedure outlined in Chapter 211, Central Venous Catheter Insertion. Inspect the leads on the pacing catheter for any breaks or manufacturing defects.

#### **Access Route**

The most direct route for internal pacemaker insertion is through a CV catheter in the right internal jugular (up to 8% failure rate). The subclavian vein (left preferred over right, and even then up to 17% failure rate) can also be used, especially for relatively long-term use, but this route of insertion may be more difficult because of the turns the electrode has to negotiate (Fig. 216-4). Brachial and femoral approaches are discouraged. The brachial approach has an increased risk of cardiac puncture and the femoral approach has an increased risk of deep venous thrombosis and infection.

#### Catheter Conversion

If necessary, insert a larger catheter into the established venous access site.

- 1. Place a guidewire down the CV access line.
- 2. Remove the catheter.
- 3. Use an obturator over the wire to enlarge the lumen.
- 4. Pass an introducer with catheter (e.g., Swan-Ganz or Cordis) assembly over the guidewire.
- 5. Remove the introducer.
- 6. Check for venous return.

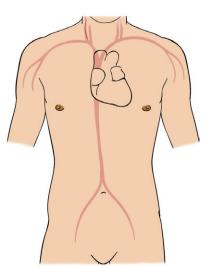

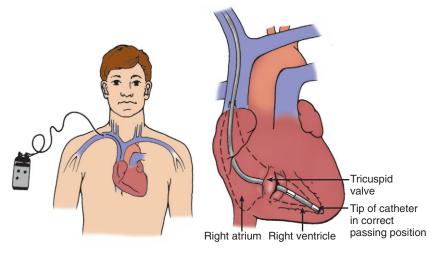

Figure 216-4 Temporary pacer in right internal jugular vein.

**Figure 216-5** Correct positioning of pacer catheter. When the tip reaches the apex, it stops moving under fluoroscopy.

#### **Pacer Placement**

**FLUOROSCOPY TECHNIQUE.** By far, the best method of temporary pacer placement involves fluoroscopic guidance of the semifloating or balloon-tipped bipolar pacing leads. Many intensive care units and some emergency departments have beds that will accommodate C-arms for fluoroscopy. If C-arms cannot be accommodated, and if time and clinical conditions permit, the patient might also be moved to the radiology suite.

- 1. Pass the catheter through the rubber diaphragm of the introducer sheath and to the 10- to 12-cm mark (10-cm segments are marked on the catheter).
- 2. If the balloon is used, blow it up and advance the catheter; it should move easily into the right atrium (RA).
- 3. Pass the tip across the tricuspid valve and advance it to the apex of the right ventricle (RV). Ask the patient to take deep breaths or to cough; this will facilitate passage across the valve. Under fluoroscopy, once the radiopaque tip is at the apex, the last 2 to 3 cm of the lead should show minimal or no longitudinal motion if an attempt is made to advance the catheter farther. The remainder of the catheter may have horizontal and longitudinal motion (Fig. 216-5), but not the tip. If a balloon is used, deflate it as soon as it passes across the tricuspid valve and washes to the ventricular wall.

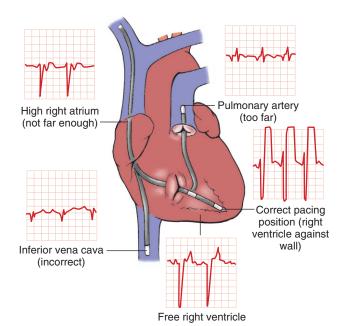

If the catheter tip curls up against the atrial wall, advance it 1 to 2 cm to create a partial loop. Next, rotate it clockwise and watch it straighten as it enters the plane of the tricuspid valve.

- 4. The best final position for the catheter tip is at the right ventricular apex. Electrodes residing in the pulmonary outflow tract or along the free wall are less stable and more likely to cause perforation.
- If a balloon is used, it must be deflated before withdrawal for repositioning.
- Coiling the proximal electrode catheter around the insertion site and firmly suturing and taping it to the skin prevents inadvertent dislodgement of the distal electrode. Using the extension cable, connect the pacer electrodes to the pacer unit.

**NONFLUOROSCOPY TECHNIQUE.** A flexible, semiflotation or balloon-tipped catheter can be advanced and positioned much like a pulmonary artery catheter (see Chapter 215, Swan-Ganz [Pulmonary Artery] Catheterization), except that the distal negative catheter electrode is attached to an ECG machine (usually the  $V_1$  lead, a unipolar lead) using a connector with alligator clips.

- 1. Connect the limb leads of an ECG machine to the patient.
- 2. Turn on the ECG machine and set it to the appropriate lead to monitor insertion (again, usually the V<sub>1</sub> lead). Use an alligator

- clip to attach the connector lead to the negative pacing catheter electrode. Next, touch the connector lead to the ECG monitor lead to confirm that the ECG is obtaining a signal. A large wave should be seen on the monitor when the connector lead touches the ECG lead.
- 3. Insert the pacemaker catheter through the rubber diaphragm of the introducer sheath and to the 10-cm mark. Using the other alligator clip, attach the connector lead to the ECG lead. If the balloon is used, inflate it and advance the catheter; it should move easily into the RA.
- 4. The change in the recorded QRS complex allows the practitioner to approximate the tip location (Fig. 216-6). Follow the same passage route: into the veins and then RA, across the tricuspid valve, and to the apex of the RV. In the internal jugular or subclavian vein, the P wave and the QRS complex are both small in amplitude and inverted. In the superior vena cava, the P wave increases in amplitude while the QRS complex is unchanged. As the electrode enters the RA, the P wave appears quite large but remains inverted until it reaches the lower RA, where it turns

**Figure 216-6** Pattern of recorded electrocardiogram from intracardiac pacemaker electrodes at various locations in the venous circulation.

- upright. As it passes the tricuspid valve, the QRS amplitude increases. When the electrode is freely floating in the RV, the QRS amplitude appears large and normal (inverted in  $V_1$  lead). The balloon should be deflated. Advance the catheter until a large, elevated ST segment is observed. This indicates the catheter is abutting the RV wall and is in the correct location.
- 5. If the catheter does not advance across the tricuspid valve, rotate it clockwise while advancing it 1 cm to flip the tip across the valve. If the catheter exits the RA and enters the inferior vena cava, the amplitudes of the P wave and QRS complex will decrease. Withdraw the catheter until the largest P wave is noted and then readvance the catheter. If the catheter exits the RA and enters the pulmonary artery, the P wave will become negative and the QRS will decrease. Withdraw the catheter until the normal right ventricular P wave and QRS complex are seen and then readvance the catheter.
- Disconnect the negative pacemaker catheter lead from the connector and attach the positive and negative leads to the positive and negative terminals of the pacemaker generator, respectively.

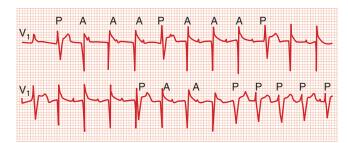

**EMERGENCY TECHNIQUE.** Unfortunately, situations frequently require placement of a temporary pacer under emergent or extreme conditions, without fluoroscopic or ECG guidance, such as during a code with the patient lying in a hospital bed (often this is necessary because the alligator clips and connector are not available for ECG guidance).

- A flexible catheter should be used, and it may be inserted blindly to about 12 cm. The catheter is then attached to the pacemaker and the pacemaker turned on.
- 2. Set the rate higher than the patient's highest native heart rate (usually 80 to 120 bpm), the amperage (ventricular output current) at 5 mA, and the mode at asynchronous (sensitivity off).
- 3. A surface or conventional ECG or rhythm strip should be running while the catheter is being passed. Capture is noted by an obviously paced rhythm seen on the surface ECG. Do not advance the catheter against resistance or more than 12 cm beyond the point at which the pacemaker was turned on. If capture does not occur at this point, withdraw the catheter and rotate it 90 degrees and readvance. Multiple attempts at passage may be necessary. When capture occurs, decrease the ventricular rate to 70 or 80 bpm.
- 4. Alternatively, the sensing indicator on the pacemaker can be used to guide placement. Advance the flexible catheter to about 12 cm, inflate the balloon, attach and turn on the pacemaker, and set it on demand mode with a rate twice the patient's highest native heart rate (again, usually 80 to 120 bpm) and the amperage at 1.5 to 2 mA. Advance the catheter, and when it enters the RV, the sensing indicator will illuminate with every other heart beat (because the pacemaker rate was set at twice the native heart rate). Deflate the balloon and increase the output to 5 mA. Slowly advance the catheter until ventricular capture occurs. Do not advance the catheter more than 10 cm beyond where the sensing indicator began to illuminate. If successful capture still has not occurred by this point, withdraw the catheter and rotate it 90 degrees. Readvance the catheter up to 10 cm. Continue to repeat the process until ventricular capture occurs and then decrease the ventricular rate to 70 or 80 bpm. Unfortunately, even experienced clinicians occasionally fail despite multiple attempts with either technique, underscoring the benefits of fluoroscopic guidance.

#### **Parameter Settings**

Determine the pacing parameters, and record each when it is set.

1. *Rate*: If the patient shows no intrinsic heart rate, set the pacing rate at 70 to 80 bpm to simulate the normal beating heart. If the patient is bradycardic, the same range can be used to raise the

**Figure 216-7** Pacing with intermittent capture. P indicates paced beats; A indicates pacer artifact without capture. (From Dahlberg ST, Benotti JR: Temporary cardiac pacing. In Rippe JM, Irwin RS, Alpert JS, Fink MP [eds]: Intensive Care Medicine, 2nd ed. Boston, Little, Brown, 1991.)

blood pressure and heart rate. Record the rate chosen after setting the machine.

2. Ventricular output: The sensitivity is the voltage used (set the sensitivity between 1.5 and 3 millivolts [mV]), whereas the ventricular output is the current generated by the pacer, adjustable from 0.1 to 20 mA. Depending on technique, start with 1.5 to 5 mA and increase until capture is seen on the monitor. After reaching the level of output necessary to capture the ventricle, large spikes are seen (Fig. 216-7) followed by bundle branch block pattern complexes (wide QRS complexes, ST-segment elevation, and T-wave inversion, depending on the lead). The bundle branch block pattern occurs because the complex originates in the ventricle. A pulse should also be palpable and it should generate a blood pressure. The ventricular output setting can then be reduced gradually, until capture is lost. The setting at which capture is lost is the pacing threshold, and this should be recorded. Resume pacing at 2 mA above this threshold. If capture occurs at less than 0.5 mA, the catheter may have become deeply embedded in the ventricular wall; be aware that withdrawal may cause perforation. If spikes are seen but no capture occurs, catheter manipulation is indicated. If levels of 5 to 6 mA or greater are required (which is common in fibrosis, but is usually a result of poor electrode positioning), attempt to reposition the electrode. If spikes and bundle branch block pattern are seen with no pulse, the possibility of pulseless electrical activity (electromechanical dissociation) must be considered. With electromechanical dissociation, the proper ACLS management protocol should be followed and there may be benefit of an emergent echocardiogram (see Chapter 225, Emergency Department, Hospitalist, and Office Ultrasonography [Clinical Ultrasonography]).

#### **Demand Pacing**

If the patient's intrinsic rhythm is inadequate, a sensing threshold must be determined with the sensitivity knob. Occasionally a sensing threshold cannot be determined when the patient has a very slow rhythm.

Sensitivity is the control on the pacer that detects the amplitude of the patient's intrinsic R wave. The most sensitive setting is 1 mV, corresponding to full clockwise rotation of the knob. In the least sensitive setting, called *asynchronous pacing*, the pacer does not "care" if there is a rhythm and functions oblivious to the intrinsic rate. The asynchronous setting should be avoided when there is an intrinsic rhythm because the additional electric spikes generated by the pacer can cause an arrhythmia.

To determine sensing threshold, first set the rate about 10 bpm below the patient's intrinsic rate. Gradually adjust the sensitivity control toward the highest sensitivity or entirely clockwise (to detect even the lowest-amplitude waves), which is known as the *full demand* setting. Pacer pulses should no longer be seen because all deflections are sensed and interpreted as QRS complexes. Every intrinsic or artifactual QRS complex should generate a flash of the

sense indicator on the pacer. At this level the pacer senses almost all electrical activity and its firing is thus prevented. In fact, T waves, occasionally P waves (if the catheter is close to the atrium), chest muscle contractions, or even artifact may prevent the pacer from firing. This is called the oversensing point. This full demand setting is obviously too high for the pacer to function. The sensitivity control should then be turned counterclockwise, changing or decreasing the sensitivity toward higher numbers until ECG pacer spikes are seen that correspond to the patient's intrinsic rhythm, regardless of their capture. This level is the sensing threshold of the pacer. The pace indicator light (if the machine has one) should also flash. For demand pacing the sensing should be set at a level halfway between the oversensing point and the sensing threshold. This level should be recorded. Keep in mind that pacers can fail to sense when the sensitivity setting on the pacer is too low, when the lead is malpositioned, or when the intrinsic signal is of poor quality.

Once pacing is performing effectively, the length of wire that has been inserted transvenously should be recorded. Secure the electrode catheter to the skin with two sutures at two sites.

#### **Confirmation of Lead Placement**

- A cross-table lateral and anteroposterior chest radiograph should be ordered. Pneumothorax should be ruled out. The tip of the catheter should be at the distal RV, in the apex, with no loops, kinks, or doublings. On the lateral view, the pacer should be to the left of the spine and slightly inferior and anterior, retrosternally.
- A 12-lead ECG should demonstrate the expected left bundle branch block pattern because of the origination of electrical current in the RV (Fig. 216-8).
- 3. The pacer pulse generator should be secured to the bed, not the patient, for at least 24 hours. It should be covered to prevent inadvertent damage to the controls.

While a temporary pacer is in place, the patient's rhythm should be monitored and a hardwire or telemetry rhythm strip should be

**Figure 216-8** Finished product: 12-lead electrocardiogram with pacer in place. (From Morelli RL, Goldschlager N: Temporary transvenous pacing: Resolving postinsertion problems. J Crit Illness 2[3]:71, 1987.)

recorded frequently. Patients should be restricted to bed rest for at least 24 hours. Aseptic technique must be maintained when the catheter is handled, and appropriate skin care should be ordered. Sterile dressing changes should follow the intensive care unit's CV line protocol. Unnecessary catheter manipulations should be avoided. Pacemaker function should be checked daily with a 12-lead ECG. A change in the morphology of the paced QRS on the 12-lead ECG may be the first sign of electrode displacement. Daily physical examination for friction rubs (a clue to perforation) or clicking noises (muscle stimulation) must be documented. Pacing threshold should also be determined daily and documented.

#### Troubleshooting: Failure to Pace

Failure to pace can occur for a variety of reasons, including—but not limited to—a faulty battery, dislodged or malpositioned leads, a loose connection, a damaged or fractured wire, electronic interference, or a faulty pacer. Some cardiac conditions cause very high pacing thresholds or preclude intrinsic pacing, including myocardial fibrosis or ischemia, drug toxicity from cardiac agents, myocardial perforation, and ventricular refractoriness from a low-grade, unsensed, intrinsic QRS complex.

If the pacer fails to work after it had been functioning previously, several questions should be considered: Has the catheter become dislodged? Are the wires loose or disconnected? Are the pacemaker settings correct? Has the battery failed? Is there electrical interference? Has the ventricle been perforated as a result of synchronous diaphragmatic or intracostal muscle contractions?

In an emergency situation, consider increasing the stimulation or pacing threshold to regain capture. Occasionally the area in the heart near the electrode has become fibrotic, requiring a higher stimulation. Also, the catheter tip could have become partially dislodged. If the problem is oversensing, that threshold should be reset.

If all else fails, another emergency maneuver is to switch the polarity of the pacer lead connections. Occasionally this technique will regain pacing, although it has not been well documented in the medical literature.

#### POSTPROCEDURE PATIENT EDUCATION

See the Postprocedure Patient Education section of Chapter 211, Central Venous Catheter Insertion. Also, if a patient will need a permanent pacemaker, see the Online Resources section of this chapter for patient education.

#### **COMPLICATIONS**

Most complications are infrequent and usually minor. Lifethreatening complications are rare. Complications are seen more frequently as a result of pacing in an emergency, especially in a critically ill patient and when the operator is inexperienced.

- Pacing system dysfunction (18% to 43% of cases for transvenous), including failure to capture or sense the R wave properly. System malfunctions are usually due to problems with connections and lead placement or inappropriate setup of the device.
- Loss of pacing (failure of pacer, lead dislodgement, fracture of pacer wire).
- Failure to recognize that the pacer is not capturing or pacing.
- Pericardial friction rub, endocardial structural damage, myocardial damage, or infarction.
- Arrhythmia.
- Diaphragmatic stimulation; chest wall stimulation.

#### **External (Transcutaneous)**

Failure to recognize the presence of underlying treatable ventricular fibrillation.

- Prolonged use is often associated with leads becoming dislodged; occasionally prolonged pacing is associated with a change in pacing threshold, requiring increased pacing current.
- Third-degree burns have been reported in children, even when large electrodes were used. The risk of a burn increases if the electrodes are placed improperly or if prolonged pacing is necessary.

#### Internal (Transvenous)

Complications include same as those for CV line insertion; see Chapter 211, Central Venous Catheter Insertion.

- Infection, including bacteremia and septicemia (up to 20% of patients developed microbiologically confirmed septicemia when the pacing wire was left in place >48 hours, and this increases risk of infection when a permanent pacemaker is placed).
- Interventricular septum or right ventricular perforation, with or without cardiac tamponade.
- Arterial or venous injury, including phlebitis and thrombosis (incidence is higher than expected).
- Pulmonary embolism.
- Air embolism.
- Electrical hazards (any extraneous currents, even microcurrents, can cause ventricular fibrillation if applied to a transvenous pacemaker catheter).

#### **PATIENT EDUCATION GUIDES**

See the sample patient education form available online at www. expertconsult.com.

#### **CPT/BILLING CODES**

- 33210 Insertion or replacement of temporary transvenous single chamber cardiac electrode or pacemaker catheter
- 36556 Insertion of nontunneled centrally inserted central venous catheter, over age 5
- 92953 Temporary transcutaneous pacing

#### **ICD-9-CM DIAGNOSTIC CODES**

- 410.01 Acute myocardial infarction, initial episode of care, anterolateral wall, can include damage such as ruptured myocardium (ST elevation)
- 410.11 Acute myocardial infarction, initial episode of care, anterior, anteroapical, or anteroseptal wall, can include damage such as ruptured myocardium (ST elevation)
- 410.21 Acute myocardial infarction, initial episode of care, of inferolateral wall, can include damage such as ruptured myocardium (ST elevation)
- 410.41 Acute myocardial infarction, initial episode of care, other inferior wall, can include damage such as ruptured myocardium (ST elevation)
- 410.71 Acute myocardial infarction, initial episode of care, subendocardial or non-ST elevation infarction
- 410.91 Acute myocardial infarction, initial episode of care, unspecified site
- 426.0 Atrioventricular block, complete or third-degree heart block
- 426.2 Left bundle branch hemiblock
- 426.3 Left bundle branch block, complete

- 426.4 Right bundle branch block
- 426.11 First-degree atrioventricular block
- 426.12 Mobitz type II block
- 426.13 Other second-degree atrioventricular block, including Mobitz type I (Wenckebach's)

# DRAWING BLOOD CULTURES

Theodore O'Connell

Bacteremia and septicemia are potentially life-threatening conditions caused by a variety of microorganisms. The successful isolation of microorganisms from blood requires an understanding of the intermittent nature of most bacteremias, the low order of magnitude of most bacteremias, and the great variety of organisms capable of causing septicemia.

Consideration must first be given to the patient's clinical status. Indications for obtaining blood cultures are outlined later. Note that 25% of patients with documented bacteremia have periods without fever. In the elderly population, the proportion is even higher, with 50% of bacteremic patients older than 65 years of age being afebrile.

Because most bacteremias are intermittent, blood collections for culture ideally should be made intermittently during a 24-hour period. Two separate blood culture sets should be collected within a 24-hour period. However, if urgent administration of antibiotics is clinically indicated, two sets of cultures from two different sites should be obtained, separated by 20 to 30 minutes if possible. Cultures should also be obtained through any vascular access devices that have been in place at least 48 hours. Each set of culture bottles has one aerobic and one anaerobic bottle.

Most bacteremias are of a very low magnitude, so an adequate volume of blood should be collected for each set of cultures. Small children usually have higher numbers (concentrations) of bacteria in the blood than adults, which means that smaller quantities of blood may be obtained from children. Appropriate volumes are noted in Table 217-1.

#### **INDICATIONS**

- Fever and unexplained alterations in mental status, functional status, or autonomic status in a previously healthy patient
- Fever and no source of infection, especially in a patient younger than 2 years of age or older than 65 years of age
- Fever of unknown origin
- Immunocompromised status with a fever and no source
- All febrile infants younger than 3 months of age
- Persistent rigors, with or without fever
- Fever, or no fever in a patient with a toxic or "septic" appearance (including unexplained hypotension, altered mental status, or shock)
- Possible infectious endocarditis (hematuria and elevated sedimentation rate)
- Serious focal infections such as meningitis, septic arthritis, and osteomyelitis
- Patients with pneumonia or pyelonephritis and need for hospitalization or with signs of toxicity

#### **CONTRAINDICATIONS**

There are essentially no contraindications to drawing blood cultures. As with any patient, blood should not be drawn through infected skin sites.

#### **EQUIPMENT**

- Alcohol pads.
- 2% tincture of iodine in 70% alcohol (alternatively, 2% iodine solution or 10% povidone—iodine [Betadine] may be used).
- Chlorhexidine (Hibiclens) may be used in the iodine-allergic patient.
- Tourniquet.
- Gloves and any equipment needed to follow universal blood and body fluid precautions.
- 21-gauge needle.
- 30-mL syringe.
- Set of blood culture bottles, aerobic and anaerobic, with labels.

#### PREPROCEDURE PATIENT PREPARATION

Drawing blood for culture does not entail any more risk than drawing blood for any other purpose. Patients should be warned about the needlestick and the potential for bleeding, bruising, and infection. Written consent for this procedure is not necessary.

#### **TECHNIQUE**

- 1. Fill in the laboratory request form and explain the procedure to the patient.
- 2. Apply the tourniquet and determine the location of the vein to be used for venipuncture (Fig. 217-1A).
- Cleanse the skin with alcohol swabs three times or until pads are free of surface dirt.
- 4. Allow the skin to dry.
- 5. Apply iodine three times in centrifugal circles from the anticipated site of venipuncture.
- 6. After the third swab, allow to dry at least 60 seconds.
- 7. Remove the protective cap and cleanse the top of the culture bottles with alcohol swabs.
- 8. Wipe off dry iodine at the venipuncture site with alcohol swabs. Do not palpate the vein or the area where the needle will be inserted after disinfecting the site. Clinicians should follow universal blood and body fluid precautions.
- 9. Obtain the required volume of blood (see Table 217-1 for recommended blood volumes by patient size).
- 10. Immediately apply pressure to the puncture site (after removing the needle) with a clean cotton sponge.
- 11. Place up to 10 mL of blood in each culture bottle. (These two bottles constitute one blood culture "set.")
- 12. Inoculate both bottles without changing needles.
- 13. Repeat at different sites or different times for the requisite number of blood culture sets.
- 14. Transport the blood cultures as soon as possible to start the incubating process.
- 15. Specimens need to be held for an extended duration when culturing blood for fungi or fastidious bacteria.

Drawn per Blood Culture Set					
Age Group	Ideal Volume per Set (mL)				
Neonates Infants 5–10 kg Children 7–20 kg Children 20–40 kg Children >40 kg Adults	I-2 2-4 3-8 I0 20-30 20-30				

#### **COMPLICATIONS**

- Bleeding
- Bruising
- Infection

#### INTERPRETATION OF RESULTS

In the case of a positive blood culture, the offending organism(s) are identified. If sensitivities have been ordered, the antibiotic susceptibility or resistance is reported.

One of the more challenging aspects of interpreting blood culture results is determining which positive blood cultures are actually

false-positive results. Features of false-positive blood cultures are outlined as follows:

- Coagulase-negative staphylococci (Staphylococcus epidermidis) and Streptococcus viridans in a single bottle in patients not suspected of having infectious endocarditis and without chronic indwelling intravenous catheters are usually contaminants.
- Corynebacterium, Propionibacterium acnes, and Bacillus species are usually contaminants, but they can be pathogens in immunocompromised hosts.
- Multiple organisms growing from the same bottle suggests contamination.
- Species that grow out after a prolonged culture have a greater likelihood of being contaminants.
- The patient's symptoms have resolved or are inconsistent with sepsis. However, special consideration must be given to infectious endocarditis, which can have an indolent course.
- A primary infected source, such as urine, yields a different pathogenic isolate.

#### **CPT/BILLING CODES**

If cultures are grown in the office and organisms identified, laboratory codes are as follows:

87040 Culture, bacterial; blood, aerobic, with isolation and presumptive identification of isolates (includes anaerobic culture, if appropriate)

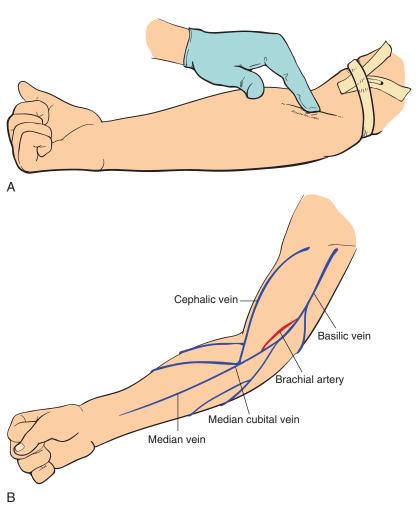

Figure 217-1 Venipuncture. A, After the tourniquet is applied, the vein is located. B, Veins in arm.

#### 1486 HOSPITALIST

87103 Culture, fungi (mold or yeast) isolation, with presumptive identification of isolates, blood

There is no specific code for drawing blood. Add laboratory handling fee (99000) to office visit.

#### **ICD-9-CM DIAGNOSTIC CODES**

038.0	Septicemia, streptococcal
038.2	Septicemia, pneumococca
038.3	Septicemia, anaerobic
038.9	Septicemia, unspecified
771.83	Bacteremia, newborn
790.7	Bacteremia

### **ACUPUNCTURE**

Victor S. Sierpina

The insertion of fine needles into the body at specific points, or "channels of energy flow," called *meridians* has been used in the treatment of human and animal disease for thousands of years. The oldest reference to this traditional East Asian medical procedure dates to 2600 BC, when fine, sharpened stone or bamboo needles were reported to be used in the treatment and prevention of illness.

Contemporary use of acupuncture has become increasingly popular. It is offered not only by traditionally trained doctors of Oriental medicine, but by allopathic and osteopathic physicians and clinicians. Patient interest and acceptance of acupuncture in the United States have resulted in its investigation and recognition by such bodies as the National Institutes of Health's (NIH) Office of Alternative Medicine. Their advisory panel recently released a consensus statement supporting the efficacy of acupuncture and acknowledging the potential benefit of acupuncture in a number of acute and chronic conditions (NIH, 2005). Furthermore, they recommended that the insurance industry consider wider coverage for this safe and effective technique. These statements have begun changing the perceptions of this ancient medical art from that of a curiosity or an "experimental treatment" to that of an acceptable procedure within medical science.

Although the exact mechanism of its action is not known, acupuncture is the most widely studied alternative therapy, and a wide variety of theories attempt to explain its effects. After use for many centuries, the traditional concept used by the Chinese and others to explain acupuncture is that it is a method of balancing qi (or chi), an invisible yet essential, ceaselessly flowing life energy that circulates silently and invisibly in the body. Because no scientist has ever measured or seen qi, only its effects can be observed. These effects are best demonstrated when the body is performing normally, an amalgamation of all the physiologic, immunologic, and homeostatic functions of a living organism. The blockage of the flow of qi, an inadequate or waning supply of it, or an excess amount of qi can all lead to conditions of pain, disease, and loss of homeostasis.

This quasi-mystical explanation is not always satisfying to the medical scientist's theorizing mind. Thus, attempts have been made over the years to derive a more robust explanation, one that is understandable in terms of Western scientific tradition and terminology. The work of Pomeranz and others showed that some of the effects of acupuncture are achieved by activating the endorphin neuropeptide system and can be blocked by the opiate receptor antagonist naloxone. Others have looked into the quantum physics realm and found parallels there in nonlocal effects, standing wave theory, and other quantum principles now used by physicists. Certain hybrid models apply Western medical and physiologic terminology to explain the effect of needling. These models discuss the ionic and electrical milieu of cells and tissues as well as the foreign body effect and the pattern of injury currents induced by needling. Additional theories explain acupuncture results as being due to a "neurogate blocking phenomenon," various neural or endocrinologic events, effects on cytokine and prostaglandin inflammatory pathways, or electromagnetic field realignment. Given the sheer range and diversity of these explanations, it is likely that acupuncture works through a number of mechanisms and perhaps is not yet fully explicable with our current science. However, its effects on humans and animals, its longevity as a healing art, and its resurgence in the Western medical community are all inductive evidence of the value of acupuncture, whatever its mechanism of action.

Although there is considerable variability among training approaches for physicians, the annual 300-hour course called Medical Acupuncture for Physicians offered by the Helms Medical Institute (1-510-649-8488; www.hmieducation.com) and Stanford University (http://cme.stanford.edu/courses) is widely acknowledged as a benchmark minimum for those wanting to practice acupuncture. Classes are offered over several months, including distance learning by DVD and video, and are designed to give practical knowledge without requiring too much time away from a medical practice. The longer, 3- to 4-year courses offered at Asian medical colleges are not usually required by states for licensure for physicians and are often impractical for the practicing clinician to complete.

Laws governing physician acupuncture are listed on the American Academy of Medical Acupuncture's website, www. medicalacupuncture.org.

Blending this ancient medical art into a medical practice can be a source of satisfaction to both professionals and their patients. It can serve as a practice builder and provide new opportunities to attract patients. With the NIH consensus panel's opinion on record, health care professionals have reason to anticipate better insurance coverage for acupuncture and a resulting increase in demand. In fact, some HMOs already reimburse for alternative therapies, including acupuncture.

#### **INDICATIONS**

Although acupuncture has been used to treat every imaginable human condition, to treat animals, and to prevent disease, most clinicians performing acupuncture find its greatest usefulness in the following conditions:

- Arthritis
- Asthma
- Back pain
- Carpal tunnel syndrome
- Dizziness
- Dysmenorrhea
- Gastrointestinal disorders
- Gynecologic problems
- Headache
- Irritable bowel syndrome
- Mental and mood disturbances
- Musculoskeletal pain
- Neuralgia
- Sciatica
- Sinusitis
- Skin disorders
- Substance addiction

- Tendonitis
- Tennis elbow
- Upper respiratory infections
- Urologic disease

#### **CONTRAINDICATIONS**

- Septic or extremely weakened patient.
- Local skin infection or loss of skin integrity (e.g., burns, cellulitis).
- Uncooperative patients or patients with delusions, hallucinations, or paranoia.
- Electroacupuncture should not be applied across the brain or heart
- During pregnancy, a number of points are to be avoided (see acupuncture references for details) because some of these points may stimulate labor.
- The umbilicus, the nipple, points over major vessels and nerves, and an infant's fontanelle are points forbidden by both classic and contemporary practitioners.
- During menses (relative contraindication).
- Patient unable to lie down (relative contraindication; sitting or standing treatments should usually be avoided, especially for first treatment).

#### **EQUIPMENT**

A variety of needles are available, ranging from very fine, 34-or 36-gauge needles, to 18-gauge needles used for veterinary acupuncture. The most commonly used needles are those from 0.5 to 3 inches in length and in the 30- to 34-gauge size. Acupuncture needles usually have solid stainless steel shafts and a copper, silver, or wound-steel-wire handle. The longer needles are used in thicker muscle groups, such as the back, buttocks, and legs, whereas the shorter, more delicate needles are used in the hands, face, and ears.

In addition to the needles, acupuncturists both in the United States and abroad, including China, now commonly use electrostimulation units (Fig. 218-1). These are small, hand-held, battery-operated units, similar in design to transcutaneous electrical stimulation (TENS) units used for pain control. Instead of the electrode pad that is used with the TENS unit, a small alligator clip

is placed on the shaft of an acupuncture needle to deliver the electrical current.

Other materials that may be used by an acupuncturist include embedded ear needles; metallic or magnetic beads; the herb moxa (*Artemisia vulgaris*), which is burned to heat the skin, needle, or acupuncture points; glass or bamboo cups used for a corollary procedure called *cupping*; small hammers with several needles on the tip (plum blossom or seven-star needles); and electrical point locators, probes, or stimulators.

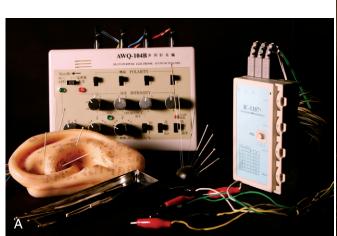

In general, four sizes of needles and a few electrostimulator devices are all that is necessary for most medical acupuncture applications. The cost of these supplies varies, but a reasonable, complete set of equipment will usually cost less than \$1000 (see the list of Suppliers).

#### PREPROCEDURE PATIENT PREPARATION

Although acupuncture is among the safest of invasive medical therapies, some precautions are needed. A thorough standard examination and diagnostic evaluation by a clinician are needed before acupuncture. Interestingly, performing these procedures often prepares the patient for acupuncture by giving him or her confidence through a known, established medical ritual—the routine physical. If the patient has never had acupuncture, the clinician should first show him or her the needles and stimulation devices. It is essential to assure the patient that the needles are sterile and disposed of after every treatment to allay fears of disease transmission. It is helpful to explain the risk of a needle reaction and the occasional endorphin rush, or "high," that follows some treatments.

Like any other medical treatment or procedure, it is wise to discuss the pros and cons of treatment, any conventional therapy options that may not have been tried, the likelihood of success with acupuncture, its possible costs, and the expected number and length of treatments. Most conditions amenable to acupuncture will show a positive response in 4 to 10 treatments. With initial treatments, the patient may experience no response, a temporary worsening of the condition, or a gradual (or even sudden) improvement. For most chronic conditions, such as low back pain, a series of 4 to 10 treatments at \$50 to \$100 per treatment is often worth the investment for the patient seeking relief.

The topics just mentioned should be discussed with every patient before initiating a course of acupuncture treatments. The initial

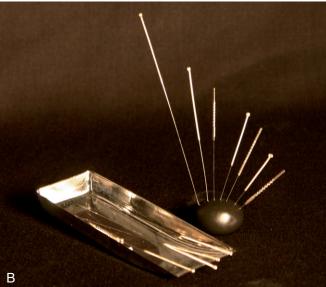

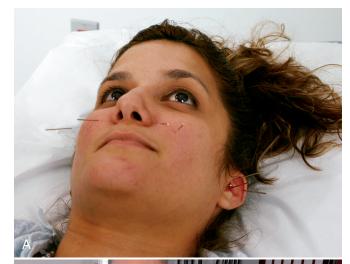

Figure 218-1 Examples of an electroacupuncture stimulator (A) and acupuncture needles of various sizes (B).

evaluation, review of records, discussion of options, and development of care plan usually occupy the entire first visit. Needle treatment is often deferred until the second visit. Usually no informed consent forms or releases are used in acupuncture therapy, although they may be useful in certain practice situations.

#### **TECHNIQUE**

Although the choice and location of points and the details of acupuncture therapeutics are beyond the scope of this chapter, the following text should give a general idea of how to interact with the patient, and how a treatment session is staged and integrated into a medical practice.

- 1. After the patient and acupuncturist agree that a trial of acupuncture is appropriate and mutually acceptable, the patient is draped or gowned. Special efforts should be made to ensure patient comfort on the treatment table, using supports such as pillows, towels, and bolsters, because the patient will be lying down for a session lasting 15 to 30 minutes or more. As noted earlier, sitting or standing treatments are avoided unless the patient is known to have tolerated them previously.
- 2. Acupuncture points are palpated on the body, extremities, ears, face, or scalp, and the needle is inserted deftly with a slight twirling motion (Figs. 218-2 to 218-4). A sufficient depth of insertion has been reached when the patient feels a slight aching sensation, indicating that the *qi* has been reached (*de qi* sensation). Needle insertion should be painless other than the mild *de qi* sensation and a tiny prick the patient may feel as the needle penetrates the skin. Although some acupuncturists wipe the area of insertion with an alcohol swab, this is not necessary. However, cleansing before needling may be prudent in certain cases (e.g., patients who have an immune deficiency or diabetes or those who are concerned or worried).
- 3. A typical treatment may require 15 to 30 needles. After all of the needles are in place, electroacupuncture electrodes are usually attached to several, but not all, of the needles. The electrostimulator is turned on and the current is gradually increased until the patient can feel a pulsing sensation. The current is then increased to the patient's maximal tolerance level and then backed off slightly (Fig. 218-5).
- 4. A timer is set, and a health care professional should remain within hailing distance to assist the patient if needed. The patient may be given a bell to ring if assistance is needed (e.g., if a needle falls out, the patient becomes uncomfortable or for some other reason needs the presence of another person).
- 5. At the end of the session, a nurse or medical assistant removes the wires and clips from the needles, removes the needles and disposes of them in a sharps container, and allows the patient to dress. The clinician or acupuncturist may return to evaluate the treatment or the patient may be discharged without further attention until the next visit. Usually the clinician is seeing or managing other patients while an acupuncture session is in progress. He or she may start another or even two more acupuncture sessions while the first is occurring, or the clinician may attend to other standard medical cases.
- 6. Follow-up treatments are done at intervals of up to 2 weeks. During return visits, the acupuncturist interviews, examines, and reevaluates the patient and his or her progress. Treatment and needle location may be altered based on the patient's response, or the same or a similar pattern may be used. As the patient starts to improve, treatment intervals are spaced farther apart. Whereas some patients obtain permanent relief from acupuncture, others may require periodic "tune-up" treatments to sustain their improvement.
- The patient's diagnosis, his or her vital signs, type of treatment, and needle application points used should be dictated into the medical record.

**Figure 218-2 A,** Example of treatment of facial and ear points. **B,** Ear acupuncture.

#### **COMPLICATIONS**

Complications are rare in acupuncture, but of those reported, the most common are local pain; swelling; hematoma formation; organ puncture; pneumothorax; metal allergy; needle reaction (fainting); a post-treatment period of euphoria; and local infections, such as perichondritis, or even more serious infections, such as endocarditis. Systemic infections, such as hepatitis and acquired immunodeficiency syndrome, have been reported as transmitted by acupuncture needle. However, poorly qualified practitioners who reused needles and did not use sterile technique were the cause of these infections.

#### POSTPROCEDURE PATIENT EDUCATION

Depending on the type of treatment, no special instructions are usually necessary. Band-Aids are not needed. Some patients,

Figure 218-3 A, Facial points used for sinus problems. B, Auricular points used for an addiction.

Figure 218-4 Needle insertion in abdomen.

Figure 218-5 Adjusting treatment settings (after checking pulse).

particularly at their first treatment, experience a euphoric spell thought to be related to endorphin release. The practitioner may instruct patients to drive carefully after a treatment or to have someone drive them home.

Some treatments are designed to increase general energy and vigor, especially in chronically weakened patients. Advice should be given to these patients to avoid heavy meals, alcoholic beverages, sexual relations, and intense exercise for about 8 hours after the treatment. This should enhance treatment benefits.

#### REFERRAL PROCESS

If you choose not to learn to use acupuncture in your practice, the clinical algorithm shown in Figure 218-6 can be very useful in selecting proper cases for referral, assessing evidence, and managing follow-up for patients who are seen by an acupuncturist outside of your practice.

#### **PATIENT EDUCATION GUIDES**

See the sample patient education form available online at www. expertconsult.com.

#### **CPT/BILLING CODES**

97810 Acupuncture, one or more needles; *without* electrical stimulation, initial 15 minutes of personal one-on-one contact with the patient

97811 Each additional 15 minutes of personal one-on-one contact with the patient, with reinsertion of needles(s) without electrical stimulation

97813 Acupuncture, one or more needles; with electrical stimulation, initial 15 minutes of personal one-on-one contact with the patient

97814 Each additional 15 minutes of personal one-on-one contact with the patient, with reinsertion of needles(s) with electrical stimulation

New codes are based on 15-minute increments, and time must be documented in the chart for billing purposes. Most patients pay out of pocket, however, thus minimizing billing procedures.

Standardized fees depend on the client population, geography, and, increasingly, the rate of insurance reimbursement. However, treatments are billed in the range of \$50 to \$100 in most cases and locations.

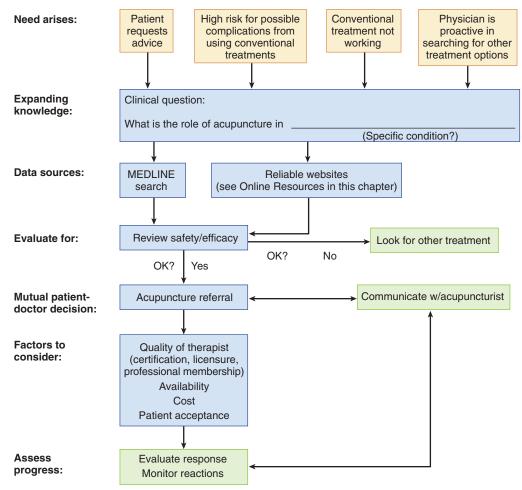

Figure 218-6 Algorithm for integrating acupuncture into medical practice.

# ALLERGY TESTING AND IMMUNOTHERAPY

Harold H. Hedges III

The primary methods of allergy skin testing are (1) *single skin prick tests* (SPT; pricking the skin at a 45-degree angle through previously placed allergens); (2) *skin puncture tests* (puncturing the skin at a 90-degree angle through previously placed allergens); and (3) using *preloaded multiple-allergen testing devices* that apply multiple allergens simultaneously. All three of these tests are confined to the epidermis. Multiple-allergen applicators have gained in popularity because of their safety, ease of use, and test reproducibility and readability. The three that are commercially available are the Multi-Test II (Lincoln Diagnostics, Decatur, Ill; Fig. 219-1), Quintest (Hollister-Stier Laboratories, Spokane, Wash; Fig. 219-2), and Omni (Greer Laboratories, Lenoir, NC).

Although considered an SPT, Multi-Test II is comparable with an *intradermal* (ID) test using a 1:1000 dilution of allergen. Several studies have shown that a positive ID skin test (1:100 dilution) after a negative SPT (using 1:20 concentrates) has little or no clinical significance; thus it is not recommended (see later discussion).

As opposed to the prick and puncture tests, the ID test goes deeper, into the dermis.

Older *scratch testing* methods are not as reproducible or reliable as SPT and are not recommended.

In vitro blood tests (e.g., radioallergosorbent test [RAST[) are performed by a reference laboratory. No "kits" are available for office testing because this procedure involves just the drawing and testing of a blood sample. It is the test of choice for patients exhibiting dermographism, hyporeactive skin, poorly controlled asthma, eczema, or any skin condition limiting the placement of skin tests.

The identification of allergens helps direct patient avoidance measures and medical therapy; it also provides the basis for immunotherapy. As Nelson and colleagues (1996) state, "Immunotherapy provides the only potentially curative treatment available because of its unique ability to change the natural history of allergic respiratory disease and Hymenoptera sensitivity. Many suggest that starting immunotherapy is a reasonable option that can provide safe and cost effective management for a substantial number of patients." Starting immunotherapy earlier in allergic conditions may prevent (rather than just reduce) the inflammatory response, prevent the development of asthma in children with rhinitis, and allow treatment to begin at lower levels of patient sensitivity. It may be the only safe modality for patients whose jobs require alertness and who cannot tolerate antihistamines (e.g., pilots, truck drivers). It is accepted that a positive SPT or in vitro test does not necessarily mean clinical sensitivity, so correlation with the clinical history is essential if immunotherapy is to be successful.

#### **INDICATIONS**

Perennial or seasonal rhinitis, rhinosinusitis, rhinoconjunctivitis, rhinitis with otitis media, and anaphylaxis from Hymenoptera stings

are the major indications for allergy testing. Patients should be tested for tree, grass, and weed pollens; mold sensitivity; and appropriate insects or animal danders. Limited food testing may be performed. There is increased risk when testing asthmatic patients and when placing them on immunotherapy, so the risk—benefit ratio must be considered carefully. Many people with asthma have concomitant allergic rhinitis, which, when treated, aids in asthma control.

#### **CONTRAINDICATIONS**

- Any condition that compromises the patient's ability to withstand the rare anaphylactic reaction (e.g., patients with uncontrolled hypertension or significant unstable cardiovascular disease)
- Although most allergic patients can be safely tested and treated by the primary care physician, an allergist should be consulted for the evaluation and treatment of patients with history of anaphylactic reactions (particularly to stinging insects), reactions to anesthetics, and difficult-to-control, moderate to severe, persistent asthma. Great caution must be exercised.
- Immunotherapy usually is not initiated during pregnancy. Allergic
  patients on maintenance therapy who become pregnant may continue the desensitization process through the pregnancy.
- Patients taking beta blockers should have alternative medications
  prescribed before they are tested and placed on immunotherapy
  because beta blockers interfere with the response to epinephrine,
  which is needed to treat anaphylaxis should it occur.
- Those with dermographism (which makes skin testing unreliable), those with chronic skin diseases that limit access to normal skin, and those (physically or psychologically) unable to communicate symptoms should be tested by in vitro testing.
- There is no specific age limit (young or old) for allergy testing to check for suspected inhaled allergens, but usually it is not done before the age of 3 years. Allergic food reactions can be detected by limited food testing (SPT or RAST). Other (nonallergic) adverse food reactions require single or multiple food elimination diets.
- Antihistamines and steroids may blunt the response to skin testing and should be eliminated before testing. Older, short-acting antihistamines should be stopped 48 hours before testing. Longer-acting antihistamines require a drug-free period of 7 to 10 days. Steroids may need to be withheld for 2 to 4 weeks. Positive and negative controls are essential, especially when these medications have been used, and help to validate skin test results. The positive control (histamine) usually responds with a 7- to 10-mm wheal (and is always read as a 3+ reaction). If the response is less, it is still being blunted by the antihistamine or other medication. In vitro tests (e.g., RAST) are not affected by any

Figure 219-1 Lincoln Diagnostics Multi-Test. (Courtesy of Lincoln Diagnostics, Decatur, III.)

antihistamines, steroids, or other medication and thus can be used at any time.

#### **SCREENING FOR ALLERGIES**

It is appropriate and cost effective to *screen* patients for allergies with a limited set of 6 to 10 allergens before applying a complete geographic panel of allergens (Fig. 219-3). A typical screen consists of a positive (histamine) and negative (glycerol-saline) control; house dust mite mix; cat; and the most tree, grass, weed, and mold allergens of the geographic area. Physicians and patients reluctant to rely on only six allergens for *screening* may use a second panel of eight allergens consisting of dog; cockroach; feathers; silk; and secondary tree, grass, weed, and mold preparations.

Always check the positive and negative control sites before interpreting the response to the allergens. When all screening test sites are negative (excluding the positive control; see Fig. 219-13), the probability of allergy is less than 3%. Approximately 50% of patients with rhinitis tested by Multi-Test or an in vitro test will have negative findings. These patients have *nonallergic rhinitis*. Identification of nonallergic triggers is critical for medical care. Decongestants (not antihistamines), nasal steroids, and nasal astemizole are the appropriate medications indicated for nonallergic rhinitis. However, roughly 50% of patients with rhinitis have an allergic basis to their symptoms. Many patients have mixed rhinitis, meaning they have both allergic and nonallergic rhinitis simultaneously.

As noted, allergy screening can be performed using either SPT or in vitro methods. Phadiatop (Pharmacia & Upjohn Diagnostics, Uppsala, Sweden) and the Multiple Inhalant Allergy screen (MIA; LabCorp, Burlington, NC) are two RAST screens using 10 allergens. In vitro screens usually have ±10 of the most common allergens, including tree, grass, weed, and molds from a geographic area; house dust mite; and cat. In vitro screens are performed by the various laboratories. A blood sample is sent to the company for testing. There is no office "kit."

**Figure 219-2** Hollister-Stier Quintest. (Courtesy of Hollister-Stier Laboratories, Spokane, Wash.)

Figure 219-3 A typical screening panel with six allergens.

When the aforementioned screening tests are negative, no further testing is needed. Screening is very cost effective in selecting out the nonallergic patient. (The Blue Cross/Blue Shield usual and customary reimbursement for SPTs is currently \$7.00 per allergen. The negative and positive controls are not reimbursed, hence the \$42 payment. The \$15 to \$25 fee for in vitro testing varies from company to company.)

A history of symptoms in early *spring* generally correlates with positive skin tests to tree allergens. Summer symptoms correlate with grass sensitivity, and *fall* symptoms correlate with weed sensitivity. In the warmer climates there is much overlap. Year-round (perennial) symptoms correlate with house dust mite, mold, or insect or animal sensitivity. Perennial symptoms with seasonal exacerbations frequently occur in the same patient.

#### PREPROCEDURE PATIENT PREPARATION

- Establish the history compatible with rhinitis or asthma.
- Explore hereditary factors, allergic and nonallergic triggers, previous and present medications, severity and duration of symptoms, secondary infections, and quality-of-life limitations caused by the symptoms.
- Perform a physical examination to evaluate for signs of atopic disease: rhinorrhea (especially if clear and combined with nasal congestion and pale blue, swollen turbinates), allergic "shiners" under the eyes, conjunctivitis, and evidence of reversible airway disease.
- Spirometry or peak expiratory flow rates are helpful to identify and follow associated asthma (see Chapter 91, Pulmonary Function Testing). Patients with poorly controlled asthma (forced expiratory volume in 1 second [FEV<sub>1</sub>] <70% of their personal best effort) should not be skin tested or receive immunotherapy until treated and stable. In vitro testing, however, is safe and recommended in this situation
- Inform patients about the nature of testing, the risk of possible reactions, the types of reactions encountered (local and systemic), and the treatment available should a reaction occur. Patients or parents of minors should sign an informed consent. (Refer to Lockey and colleagues, 2004.)
- Instruct patients to avoid older, short-acting antihistamines 48
  hours before skin testing. Longer-acting antihistamines should be
  avoided 7 to 14 days before testing. Remember, the positive histamine control must produce a 7- to 10-mm wheal to validate skin
  testing.
- Explain the frequency and duration of immunotherapy (weekly or biweekly injections for 3 to 5 years), the expected response, and the criteria for discontinuation (symptom-free control with little or no medication and no increase in symptoms with increasing intervals between injections).

#### **EQUIPMENT**

#### For Skin Testing

- Multiple allergen applicators and loading docks (Multi-Test II, Quintest, Greer)
- Individual applicators for the occasional testing of one or two allergens (Duotip [Lincoln Diagnostics], Morrow Brown Needle

[Alkaline Corporation, Oakhurst, NJ]); or a tip from a multipleallergen applicator can be broken off and used separately

- Alcohol sponges to clean the testing site
- 30 to 50 standardized or 1:20 weight/volume [w/v] allergen concentrates identified for the specific geographic locale by published data or suggested by providers of allergy diagnostics (house dust mite comes only as a 1:100 dilution as the concentrate)
- Histamine phosphate (2.75 mg/mL) for the positive control and saline for the negative control
- Recording form (Fig. 219-4)
- Black skin-marking pen
- Timer capable of timing at least 20 minutes
- Millimeter ruler
- EpiPen, Ana-Kit, or epinephrine; and albuterol
- Resuscitation equipment in the rare event of anaphylactic reaction (the same as that for giving any injections in the office; see Chapter 220, Anaphylaxis)
- Disposable tuberculin syringes fitted with a 26- or 27-gauge needle for the "vial test" (see the section on Intradermal Testing and the Vial Test)

### For Radioallergosorbent Testing or Other in Vitro Tests

- Equipment for drawing blood
- Mailing packages or instructions provided by the RAST laboratory

#### **TECHNIQUE**

#### **Skin Prick and Puncture Tests**

Skin *prick* tests are performed by placing a drop of allergen concentrate (usually 1:20 w/v) on the arm or back, then pressing a needle through the drop into the epidermis at a 45-degree angle. The tip of the needle is then lifted up, producing the pricking sensation. If performed correctly, no bleeding should occur (Figs. 219-5 and 219-6A). The skin *puncture* test is similar, but the skin is punctured at a 90-degree angle (Fig. 219-6B). Several *skin testing devices* were listed previously. The use of Multi-Test II is described in detail here because it has been found to be safe, easily learned, reproducible, and reliable. A videotape of the procedure is available from Lincoln Diagnostics.

#### **Multi-Test Applicator Method**

Multi-Test II is a sterile, disposable, multiple-test applicator used to apply eight allergens simultaneously. Although considered an SPT, its reliability is comparable to ID techniques using a 1:1000 dilution of allergen. Laboratories that supply the allergen concentrates will help determine the most relevant allergens for the patient's geographic area based on established patterns. The system consists of plastic applicators and the Dipwell tray (Fig. 219-7).

#### Loading the Dipwell Tray

- 1. Establish a master list of allergen panels (each containing eight allergens) to be tested and enter them on the recording form. It is crucial to load each allergen in the same test well each time. Make copies of this list for recording test results and refer to it when replenishing allergens.
- 2. Label (number) each panel A, B, C, D, etc.
- 3. Allergen panels are made by adding 1 mL (enough for 100 applications) of each allergen concentrate (1:20 w/v in 50% glycerin or standardized extract) to each well numbered 1 through 8. Applicator heads are numbered 1 through 8 also and correspond to the numbered wells. Each Dipwell tray accommodates three allergen panels, each with eight testing heads (see Fig. 219-7).

4. Panel A (*screening* panel) contains the positive control in well A1 and the negative control in well A8. A2 through A7 contain the most common tree, grass, weed, and mold allergens from a geographic area, plus house dust mite mix and cat.

NOTE: This panel will identify over 95% of those in the allergic population. A negative (except for the positive control) screen indicates a nonallergic cause of rhinitis or asthma. No further allergy testing is indicated. This reduces the cost of total allergy testing. When the screen is positive, additional allergens of the geographic area are tested (usually 30 to 40). An additional panel can also be used to check for allergies to common foods (e.g., milk, corn, wheat, egg, soy, sugar, baker's yeast, and pork).

5. Trays are stored in the refrigerator and stack easily.

#### Application of Multi-Test

- 1. Place the Dipwell tray, which has been filled as noted previously, on a flat surface with the "cradle" for the "T" handle facing away from you.
- 2. Remove the sterile applicator from the package (held with the blue dot at the top) by pulling the label at the blue dot. This positions the "T" handle away from you for correct placement in the Dipwell tray (Fig. 219-8).
- 3. Place the applicator in the loaded Dipwell tray (see Fig. 219-7). The applicator now has the allergen on the respective tips.
- 4. Cleanse the skin with an alcohol wipe and allow it to dry.
- Mark (number) the test sites on the skin corresponding to the placement of the applicators (A, B, C, D, etc.) with a black skinmarking pen.
- 6. Apply panel A (screening panel) to the volar surface of the forearm (supported with a pillow to keep the arm flat) with the "T" handle toward the patient's head (Fig. 219-9). Apply with a rocking motion, to and fro and side to side. When applied with correct pressure, a footprint of each testing head will be visible. No bleeding should occur; if it does, reduce the amount of pressure applied. The correct amount of pressure will be realized after several applications.
- 7. A positive reaction to any one of the tree, grass, weed, or mold allergen(s) is followed by testing all remaining significant allergens of the area suggested by history. Total number is variable from area to area, usually 20 to 40. These are placed on the patient's back with the patient lying face down and can be applied at this visit (Fig. 219-10). Sites must be kept flat to prevent allergens from running and contaminating other sites. Hairy sites should be avoided because this interferes with readability.

#### Interpretation of Results

See Box 219-1. Positive responses are noted by wheals. Erythema may be present but is not used in scoring.

- The wheal is the white or gray raised area at the test site. This
  wheal may be surrounded by an area of erythema called the *flare*.
  The size and shape of the *wheal* only are used in scoring reactions
  (see Box 219-1) and are noted on the recording form in rhe corresponding position.
- The wheal produced at the positive (histamine) control site (Fig. 219-11), usually 7 to 10 mm in an adult and 6 mm in a child, is read and recorded as a 3+ reaction. Should the reaction at the positive control site be less than 7 mm or more than 10 mm, it should always be scored as a 3+ reaction, and should be read and recorded at 10 minutes because it will begin to fade. Other sites should be read at 20 minutes.
- Reactions comparable with those at the negative control site (saline or glycerol-saline) are negative. It is not unusual to see a small wheal (1 to 3 mm) at the negative control site (Fig. 219-12). 2+ reactions are generally 3 to 5 mm in size, and 3+ reactions 5 to 7 mm. Reactions read as 4+ are greater than the

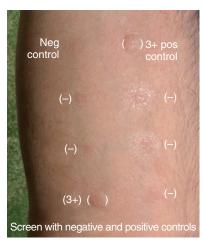

Figure 219-10 Additional panels on patient's back.

# Box 219-1. Scoring of Multi-Test (Used in Fivefold Dilution Systems)

Multi-Test is scored by comparing the reaction of allergens to the negative (glycerol–saline) and positive (histamine  $1\ mg/mL$ ) controls applied at the same time and in the same general location.

- O No reaction or a wheal up to 3 mm in size may occur at the negative control site
- 1+ Wheal larger than the negative control, usually 3–4 mm
- 2+ Wheal 5-7 mm
- 3+ Wheal 7–10 mm (size of the positive control)
- 4+ Any reaction with a wheal larger than the positive control without pseudopods
- 5+ Any reaction larger than the positive control with pseudopods

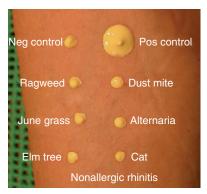

**Figure 219-11** Example of a positive allergy screen (3+ reaction). A positive reaction at the tree, grass, weed, or mold site dicatates completing local allergy panels.

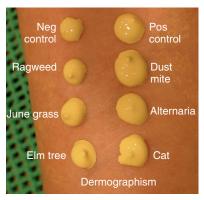

**Figure 219-12** Scoring results. See text for explanation. The negative control in the left upper corner shows a 1+ reaction.

reaction at the positive control site but retain their circular form. Reactions read as 5+ are larger than the positive control site with spreading pseudopods.

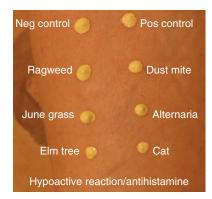

- Reactions equal to or greater than the positive (histamine) control site generally correlate the best with history of exposure to allergic triggers. 2+ reactions correlate less, and 1+ reactions even less. Correlation of all test responses to history is important in compounding immunotherapy sets.
- When the positive control is positive and all other tests are negative (Fig. 219-13), nonallergic rhinitis or asthma is present. This result occurs 50% of the time.
- Dermographism (Fig. 219-14) should be suspected when all tests are positive, including the negative control. Such patients must be tested by RAST.
- When reactions at all test sites are negative (Fig. 219-15), including the positive control site, suspect antihistamine or other medication, which may decrease the skin response.
- Results of tests are recorded (see Fig. 219-4), and a signed copy is the prescription sent to the laboratory for compounding immunotherapy (see later discussion).
- When house dust mite (Fig. 219-16), cat (Fig. 219-17), or both, are the only positive reactions, no further testing need be done at this time. Avoidance measures and immunotherapy are instituted for either or both of these allergens. House dust mite avoidance includes covering pillows and mattresses, dusting regularly, and removing stuffed animals, carpets, and overstuffed furniture. Bedding should be washed weekly with water at 130° F. Lowering humidity to below 50% is helpful. HEPA filtration helps remove small particulate matter. Ideally, cats should be eliminated from

**Figure 219-13** Nonallergic allergy screen. Positive and negative controls are appropriate; all other test sites are negative. The diagnosis is nonallergic rhinitis or asthma.

**Figure 219-14** Dermographism. Negative control is positive and all other test sites are positive.

**Figure 219-15** Positive (histamine) control is nonreactive, which invalidates skin response at other test sites. Suspect antihistamine or other medications.

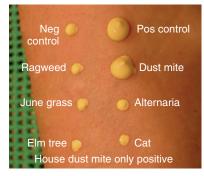

Figure 219-16 House dust mite is the only positive.

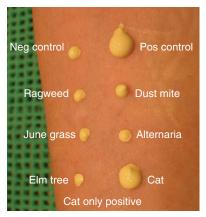

Figure 219-17 Cat is the only positive.

**Figure 219-18** Allergic rhinitis. Pseudopod is best seen with the *Alternaria* allergen.

the home, but it has been shown that less than 25% of patients or families comply. (At the very least, cats should be kept out of the bedroom and off the bed.) Weekly washing of the cat will decrease the allergen load. Later, additional allergy testing can be done if symptoms do not improve.

- Pseudopods (Fig. 219-18) occur frequently and are recorded as 4+ or 5+ reactions.
- Testing for other nonpollen allergens, such as dog, cockroach, feathers, and laboratory and farm animals, may be suggested by history.

#### Complications

- Itching at the positive test sites is expected. Highly allergic
  patients may have rapid and large skin responses and will begin
  to show whealing, erythema, and itching within minutes. These
  individual reactions should be wiped clean with alcohol, being
  careful not to contaminate a nearby test site. These will proceed
  to react despite wiping and can be treated with oral antihistamines or steroid creams if necessary. The reaction will usually
  resolve in 30 minutes to 1 hour.
- Rarely, systemic symptoms occur that may include hives, urticaria, itching of the roof of the mouth, a sensation of throat closure, shortness of breath, an increase in presenting symptoms (sneezing, rhinorrhea, or wheezing), and anxiety. All allergens should be removed with alcohol. Give 50 to 100 mg of diphenhydramine (Benadryl) orally or intramuscularly and observe closely, monitoring vital signs. Epinephrine, 0.3 mL (1:1000 dilution) for adults and 0.1 to 0.15 mL for children, should be nearby and used as needed if symptoms proceed to anaphylaxis. This occurrence is very rare. In addition to epinephrine, maintenance of the airway, correction of hypotension, and other general measures are used for treatment. Bronchodilation per inhaled albuterol should be given if asthma is precipitated. Monitor the patient's general condition, including blood pressure and respiration using peak flow measurement or spirometry, for several hours as needed. Transfer to an emergency department for more intensive help may be indicated (see Chapter 220, Anaphylaxis).
- False-negative results.
- When there is no reaction whatsoever at the positive control site, hypoactive skin due to antihistamines, steroids, or other medications should be suspected. The clinician should retest after an appropriate time off medication or consider an in vitro test, which is not affected by any medication.
- Delayed reactions (usually at mold sites) may occur up to hours after testing and last for 2 to 7 days. This reaction is an inflammatory response rather than immunoglobulin E (IgE) mediated, and it does not respond to immunotherapy. Local steroids may be helpful.

#### Intradermal Testing and the Vial Test

Historically, ID testing has followed negative or equivocal SPT results when the history strongly indicates a particular allergen. Studies have questioned the presence of clinically significant sensitivity if the SPT is negative but the ID test is positive. The use of positive ID tests after negative SPTs may not be an appropriate basis for selecting patients for immunotherapy. An ID test is used for the "vial test" before starting immunotherapy. The vial test affirms the safety of the immunotherapy set. It is needed only with the initial vial. The clinician should create a 4-mm ID wheal (Fig. 219-19) by injecting about 0.03 mL of the weakest vial (1:100,000 dilution) on the upper outer arm, using an allergy syringe and a 26- or 27-gauge needle. The test is read in 15 minutes. Growth of the ID wheal beyond 15 mm indicates increased sensitivity, and a further 10-fold (1:1,000,000) or 5-fold dilution of the vial is necessary. The clinician should take 0.5 mL of the allergen vial and add it to 4.5 mL of phenolated saline (diluting fluid) and repeat the vial test. Rarely, the vial test may cause reproduction of presenting symptoms (e.g., sneezing, rhinorrhea, congestion, or asthma). This recurrence indicates increased exposure to an allergen(s) in the mix that may have pollinated since testing and initiation of immunotherapy. Further dilution of the immunotherapy may be indicated.

#### Radioallergosorbent Blood Test

A reference laboratory processes in vitro tests. The same principles of *screening* apply as for SPT, and most laboratories will provide a geographic screening panel before completing an extensive specific regional in vitro panel; if not, one can be designed based the allergens in the clinician's local area. A negative in vitro screen requires no further testing. In vitro testing is not affected by any medication. Box 219-2 shows indications for in vitro testing.

In in vitro testing, an allergen is coupled to a paper disk or placed in a cellulose suspension to which the patient's serum is added. An antigen—antibody complex is formed that, when tagged with radio-active anti-IgE, forms an antigen—antibody—anti-IgE complex scored by a gamma counter. A grading system provides quantifying levels of IgE antibody on which immunotherapy is based. In vitro—based immunotherapy uses either 5-fold or 10-fold dilutions. In vitro laboratories usually provide immunotherapy sets or will suggest an immunotherapy-compounding laboratory. In vitro testing is efficacious. As with skin testing, results must be interpreted in light of the clinical history.

In vitro testing is an accepted method of testing for specific allergies and can be used by physicians who do not want to perform skin testing.

Figure 219-19 A 4-mm intradermal wheal for the vial test.

# Box 219-2. Indications for Radioallergosorbent Testing

Atrophic or very young skin
Dermographism
Extensive eczema or other dermatoses
History of anaphylaxis
Immunodeficiency disorders
Long-acting antihistamines, steroids
Presence of beta blockers
Unstable cardiac condition
Unstable or severe asthma

#### **ADVANTAGES OF SKIN TESTING**

- The patient can be tested and results known within minutes, whereas in vitro results may not be available for a week or longer, depending on the laboratory.
- The patient sees and experiences the reaction, which reinforces the need for avoidance. This is especially helpful in house dust mite avoidance and cat or dog allergy.
- There is much less difficulty with insurance companies over payment for skin allergy testing. A significant number of HMOs and other insurance carriers will deny payment for in vitro testing.
- In vitro testing is more expensive than SPT (\$3 to \$4 per skin test versus \$8 to \$15 per RAST).

#### POSTPROCEDURE PATIENT EDUCATION

Avoidance procedures and medications are prescribed where appropriate. Brochures describing general allergen avoidance and specific house dust mite and animal dander measures are readily available. Immunotherapy is considered an adjunct to treatment.

#### **IMMUNOTHERAPY**

Immunotherapy is indicated based on the demonstration of immediate hypersensitivity by SPT, Multi-Test, or any in vitro test that correlates with the patient's history and physical findings. This correlation is imperative for success. When beginning therapy on a patient for the first time, perform an ID test (the vial test) as noted previously. Increasing amounts of allergen are given subcutaneously until the highest tolerated dose is reached.

Conventional immunotherapy is based on a 10-fold dilution system and is started at 0.1 mL of 1:100,000 dilution of each allergen. Injections are graduated (0.1, 0.2, 0.3, 0.4, 0.5 mL) weekly through dilutions of 1:100,000, 1:10,000, 1:1000, and 1:100 until maintenance is reached. Some laboratories use a fivefold dilution system (1:325,000, 1:62,500, 1:12,5000, 1:2500, 1:500, 1:100) for immunotherapy. The maintenance dose in either system is the highest tolerated dose that can be attained without causing a significant local (painful knot or erythema lasting more than 24 hours) or systemic reaction. Some patients may not be able to tolerate injections in the 1:100 dilutions because of local or systemic reactions, but immunotherapy at lower dilutions usually will be effective for them. Using the fivefold dilution system, Multi-Test and in vitro testing allow the starting dose to be tailored based on the degree of sensitivity to the allergen. The higher the sensitivity, the more dilute the starting dose; the lower the sensitivity, the more concentrated the starting dose. Immunotherapy is usually started at a level 5 to 25 times weaker than the test scores, and then graduated until maintenance is reached.

Based on testing, an allergy laboratory will compound an immunotherapy set consisting of four vials each containing increasing

concentrations of all the relevant allergens. If more than 12 allergens are to be included, 2 sets are needed. As a clinician's allergy practice grows, compounding immunotherapy in the office can be considered. This requires additional space and personnel. By law, immunotherapy sets made by commercial laboratories are "quarantined" for 2 weeks to ensure sterility. This does not apply in office compounding. Phenolated saline with glycerin or glycerinated saline is used as the diluent in mixing, providing ample sterility and stability.

Escalation of immunotherapy (Box 219-3) proceeds on a weekly schedule with doses adjusted as needed because of local or systemic reactions. Increasing symptoms and skin responses that occur during a pollinating season may require slowing or holding of escalation until pollination ceases. As the season passes, escalation can then proceed with no further problem. Local swelling, whealing, or "knot" formation greater that 2 cm lasting more than 24 hours is considered significant. The subsequent dose should be reduced to one not causing a reaction and escalated at a slower rate for patient comfort. Doses for smaller local reactions of swelling and redness

### Box 219-4. Reasons for Allergy Treatment Failures

Development of new allergens
Erratic dosage schedule
Inaccurate diagnoses
Inadequate dose of immunotherapy
Incomplete diagnoses (allergic and nonallergic factors)
Immunotherapy dose beyond the optimal dose
Lack of appropriate patient education
Nonallergic food and chemical sensitivities
Noncompliance with avoidance
Noncompliance with medication
Rhinitis medicamentosa

should be repeated or reduced as tolerated. *Immunotherapy should be omitted or delayed* (1) when a febrile illness is present, (2) when the patient is extremely fatigued, (3) after acute exacerbation of allergic symptoms during a pollinating season, (4) or during or after an asthma attack. The peak expiratory flow rate should be above 70% of the patient's personal best effort. Asthmatic patients should be free of wheezing, cough, or shortness of breath before being tested or receiving an allergy injection. Asthmatic patients should monitor their own status with a peak flow meter.

Actions to prevent untoward reactions and anaphylaxis during immunotherapy include the following:

- Evaluate the patient's condition before injection.
- Minimize the chance of errors in dosing and administration by checking and rechecking the patient's dosing schedule and reactions to previous injections.
- Have the patient identify the vial to be used by name and birthday on the vial.
- Use more dilute allergen in highly sensitive patients (by history or testing).
- Observe patients in the office for 20 to 30 minutes after injection.
- Check the patient and injection site before allowing the patient to leave.
- Reduce the first dose of newly prepared extracts by half.
- Reduce the dose when local or systemic reactions occur.
- Avoid shots to asthmatic patients whose peak flow is less than 70% of their personal best effort.
- Avoid immunotherapy in the presence of a febrile illness.
- Avoid giving immunotherapy to patients on beta blockers.

About 80% of allergic patients respond to immunotherapy, whereas some 20% show little or no response (Box 219-4). Maintenance doses should be continued for 3 to 5 years, and the time between doses increased to 2 weeks after the first year, then 2 to 4 weeks after the second year, with symptom return used as the guide. The patient may miss doses in the buildup and maintenance phases of immunotherapy. Guidelines for treatment after missed doses are found in Boxes 219-5 and 219-6.

Drop dilution by full 10-fold (i.e., if
maintenance is 0.5 mL of vial A [1:100
dilution], drop back to 0.5 mL of vial B
[1:1000 dilution])

Attempts to discontinue immunotherapy can be made after 3 to 5 years if the patient is symptom free. The interval between injections can be lengthened from every 2 weeks to 3 or 4 weeks. If there is no exacerbation of symptoms after 6 months to 1 year, immunotherapy may be discontinued. Approximately one third of patients will return within 2 years to restart their immunotherapy program.

On completion and discontinuance of a program after 5 years of therapy, one third of patients may return to restart immunotherapy because of return of symptoms. Reasons for allergy treatment failures are given in Box 219-4.

#### Sublingual Immunotherapy

Sublingual immunotherapy (SLIT), first described in 1934 in the United States, is being increasingly recognized by U.S. physicians as an alternative to allergy shots. It is a common practice in European countries, especially in Italy and France. The safety and efficacy of SLIT are well documented in peer reviewed journals in the United States and abroad. SLIT is an evidence-based practice and recommended by the World Health Organization and the Cochrane Review. There has never been a death or serious anaphylactic reaction reported in patients using SLIT. A Joint Task Force of the American Academy of Allergy, Asthma, and Immunology (AAAAI) states, "Despite clear evidence that SLIT is an effective treatment, many questions remain unanswered, including effective dose, treatment schedules, and duration of treatment. SLIT does appear to be associated with few serious side effects" (Cox and colleagues, 2006).

At present, SLIT is an off-label use of immunotherapy. Allergens used for compounding SLIT are the same as those used for subcutaneous administration and are approved by the U.S. Food and Drug Administration (FDA). Low-dose and high-dose treatments have been shown to be effective. Efficacious weekly doses are nearly identical to those used in subcutaneous immunotherapy (SCIT). SLIT is used for 3 to 5 years before discontinuing it, similar to SCIT. The route of administration is the only significant difference.

In addition to its efficacy and safety profile, *advantages of SLIT* include the following:

- Sublingual drops can be given at home daily.
- The cost of preparation of sublingual drops is similar to that of injections.
- The cost of allergen administration decreases because no injection is necessary.
- There is no loss of time or income or inconvenience incurred in driving to and from an office to obtain an allergy injection, wait for the injection, wait after the injection, and return to work.
- There is no loss of time from school or missing after-school activities to get an allergy shot.
- There is no needle fear, as seen in children (and some adults).
- There is no erythema or painful local reaction at the injection site.
- SLIT can be used in children 3 years of age and older.

Studies are ongoing to gain FDA approval for SLIT. When SLIT is approved and covered by insurance, many more patients will be able to benefit from immunotherapy.

The disadvantages of SLIT are few:

- Doses have to be given on a daily basis rather than weekly.
- It may be difficult to get children to hold a sublingual dose in the mouth for 30 seconds or longer.
- The immune response may be somewhat slower than with SCIT.

#### Labeling and Storage of Extracts

- Each vial of extract should be labeled with the patient's name, chart number, birth date, expiration date, and dilution
- Vials are stored in the refrigerator overnight but may be kept out and readily accessible for daily use.
- Dilutions should be discarded and remade after 6 months if not used. Glycerin is added to ensure stability.
- 2.5-mL vials are used in sets for escalation of doses (five doses will be used in 5 weeks [0.1, 0.2, 0.3, 0.4, 0.5 mL = 1.5 mL]). The remainder may be used to repeat doses if necessary, or simply
- Ten dose vials (number of milliliters [usually 5 mL] will vary depending on the maintenance dose) are formulated for maintenance therapy.

#### **Summary**

Studies have shown beneficial effects on acute allergic disease as well as long-lasting symptom control after a successful course of immunotherapy. The measurable anti-inflammatory influences of immunotherapy do not occur with antihistamines and steroids, suggesting that immunotherapy should be used earlier and more often in the treatment of allergic rhinitis and asthma.

### **ANAPHYLAXIS**

Daniel J. Derksen

Anaphylaxis is an acute and serious allergic reaction in response to antigen exposure in a previously sensitized patient. It can be encountered after administration of intramuscular (IM) antibiotics; vaccines; contrast material, such as intravenous pyelography or computed tomography contrast; local anesthetics; allergy injection in the office setting; or exposure to latex. Patients may also report to the physician's office with a clinical picture of anaphylaxis after being bitten by an insect (Fig. 220-1) or snake or exposed to some other allergen (e.g., pollen, latex, certain food products). The source of the allergic reaction may be unknown to the patient.

Medical procedures frequently require injections or use of foreign materials. The clinician must be prepared to treat the rare but serious complication of anaphylaxis.

#### **DIAGNOSIS**

Depending on the severity of reaction, patients may have a variety of symptoms, including swelling, rash, urticaria, pruritus, dyspnea, abdominal pain, vomiting, and decreased blood pressure from baseline (Figs. 220-2 and 220-3). As the anaphylaxis proceeds, respiratory compromise may occur with laryngeal edema, bronchospasm, and hypoxia. The patient may progress into shock as manifested by hypotension, bradycardia, peripheral vasodilation, and mental status changes. If the physician does not take immediate steps to reverse the anaphylactoid reaction in the final stages, vascular collapse and death can occur within minutes.

Vasovagal reactions (e.g., fainting and seizure-like activity) and injection of intravascular anesthetic that can cause lightheadedness and ringing in the ears may be confused with an anaphylactic response.

#### **EQUIPMENT**

Physicians and practitioners should be prepared to treat anaphylaxis in the office, especially if any injections are given. A collection of medications and equipment, the "crash cart," can be gathered and placed in one area. Alternatively, a fishing tackle box or medical emergency kit can be made. The simplest and best-organized method is to use commercially available Banyan kits (Fig. 220-4). These kits, similar to suitcases, are stocked with various medications. They vary in size, contents, and cost (\$800 to \$1000). The Banyan Stat Kit 900 is essentially a portable crash cart, lacking only a defibrillator. The specifics on medications and equipment needed are too extensive to detail in this chapter. The Banyan Corporation provides check sheets that can be reviewed regularly to reorder out-of-date stock (see the Suppliers section).

Whether the commercially available kits are used or a do-it-yourself collection is assembled, the entire office staff must know where the kit is stored. One person must be in charge of keeping the medications current. Drugs cannot be borrowed from this kit for other purposes.

The physician in charge of office procedures must be prepared for emergencies. Assembling a crash cart or obtaining a Banyan kit

may appear expensive, but it is a good practice to have one available and is an inexpensive form of malpractice coverage in the event of an emergency.

#### **TECHNIQUE**

Patients who exhibit signs and symptoms of anaphylaxis should be treated immediately. In the earliest stages, anxiety, swelling, urticaria, pruritus, and mild dyspnea respond quickly to *epinephrine*. The dose can be 0.3 to 0.5 mL of a 1:1000 solution, given subcutaneously every 20 to 30 minutes as needed (to a maximum of three doses). In the milder reactions, antihistamines such as *diphenhydramine hydrochloride* (Benadryl), 25 to 50 mg by the intravenous (IV), IM, or oral (PO) route every 6 hours, can be given. Some suggest using both histamine type 1 and type receptor antagonists (H<sub>1</sub> and H<sub>2</sub> blockers), such as 50 mg of diphenhydramine and 50 mg of ranitidine, may be more effective than diphenhydramine alone. Systemic steroids can be given as a prednisone taper, beginning with 30 to 60 mg the first day and gradually tapering to nothing over a 2-week period.

In truly emergent situations, give 100 mg methylprednisolone (Solu-Medrol) IV. For life-threatening reactions, 5 mL of a 1:10,000 solution of epinephrine should be given IV over 10 minutes and repeated every 5 minutes as needed. In addition, consider summoning an ambulance. Patients on beta blockers may exhibit more severe anaphylactic symptoms and be refractory to epinephrine. Administration of glucagon (1-mg ampule), atropine (1 mg IV), or isoproterenol (0.1 mg/kg initially) may be necessary to stabilize patients on beta blockers who do not respond to epinephrine.

Physicians should consider basic life support (BLS) and advanced cardiac life support (ACLS) training and certification as appropriate if administering medications or therapies that might cause anaphylactic reactions. If the patient responds rapidly to epinephrine and has no further symptoms, a shorter monitoring period may be possible. For those patients refractory to treatment, or those requiring multiple doses, it may be necessary to be more aggressive, including summoning an ambulance to an emergency department, while following BLS and ACLS protocols until the patient is safely transported.

Patients with anaphylaxis or anaphylactoid reactions must be observed for an appropriate period of time after treatment of a reaction to ensure that there is no recurrence.

NOTE: A quick way to administer epinephrine is to have a preloaded syringe system of epinephrine (e.g., *EpiPen Epinephrine 0.3 mg Auto-Injector* for those weighing more than 30 kg [66 lbs], *EpiPen Jr. 0.15 mg Auto-Injector* for those weighing 15 to 30 kg [33 to 66 lbs], and *Ana-Kit Anaphylaxis Emergency Treatment Kit 1-mL* syringe) available in the office. This system eliminates the delay involved in drawing up epinephrine in a syringe before administration. Appropriate examination and treatment rooms should have one of these injection systems taped to a cabinet door for easy accessibility.

**Figure 220-1** Insect bites, such as those caused by kissing bugs (Reduviidae kissing bugs), can cause anaphylactic reactions in a small percentage of the population. The reaction may start as urticaria (hives) at the site of the bite.

#### PREVENTION WITH PREVIOUS HISTORY

Some patients may require tests that necessitate the use of known allergens. For example, patients may require a computed tomography scan with contrast material that previously caused urticaria, dyspnea, or other signs of early anaphylaxis. If an alternative contrast agent cannot be used and the test is critical to the diagnostic work-up, the patient can be counseled about the risks, asked to sign an informed consent form, and premedicated with Benadryl and steroids to minimize the risk of an anaphylactic reaction. This premedication can be done with 50 to 100 mg of Benadryl orally and 100 mg of hydrocortisone or 50 mg of methylprednisolone (Solu-Medrol) intravenously; both the oral and intravenous forms of premedication are given 1 hour before the procedure. The patient should be observed carefully for at least 6 hours after the procedure.

For patients with a history of allergies to local anesthetics, a few simple steps need to be followed. Allergies have been reported to ester drugs (e.g., procaine [Novocain]) but not to amide derivatives (e.g., lidocaine [Xylocaine]). If someone is suspected of having an allergy to a local anesthetic, the clinician should use an amide drug from a single-dose vial. Single-dose vials do not contain any preservatives (parabens), which can also be the source of allergy. To date, there have been no reported allergic reactions to amide local anesthetics from single-dose vials. It is still judicious, however, to observe the reaction to a small wheal of injected solution (0.05 mL) for 10 to 15 minutes before injecting a larger volume.

**Figure 220-2** Urticaria. Without prompt treatment, urticaria can quickly progress to angioedema.

Figure 220-3 Angioedema of the left arm and generalized anaphylaxis.

#### **PRECAUTIONS**

Procedures and medications that could result in anaphylaxis should not be administered unless the office is equipped to deal with this complication. At a minimum, the office should be able to administer subcutaneous epinephrine, supply supplemental oxygen, and provide ventilation to the patient until emergency services can arrive. In general, procedures and medications that carry a high risk of anaphylaxis should be followed by an appropriate observation period after the procedure to watch for signs and symptoms.

**Figure 220-4** Banyan kit. (Courtesy of Banyan International Corporation, Abilene, Tex.)

#### **POSTPROCEDURE PATIENT EDUCATION**

Sensitized patients should receive detailed patient education. Such patients should be encouraged to wear a medical identification bracelet that identifies the agent that could cause anaphylaxis (e.g., penicillin, bee sting, intravenous pyelography contrast). Some patients with recurrent, severe anaphylactoid reactions should carry a kit with them (containing 1:1000 epinephrine that can be injected) so that initial treatment can begin without delay. For example, a beekeeper with a known sensitivity to bee stings and who refuses to explore a new profession should be encouraged to carry a kit. Patients with previous anaphylaxis should be instructed to seek prompt medical attention for the following symptoms:

- Shortness of breath
- Swelling of eyes, legs, or hands
- Dizziness
- Sensation of swelling in the throat
- Raised, red rashes (urticaria)
- Change in mental status

## ANTIBIOTIC PROPHYLAXIS

Coral D. Matus • Scott F. Ross

### ANTIBIOTIC PROPHYLAXIS FOR INFECTIVE ENDOCARDITIS

The publication of new American Heart Association guidelines for the prevention of infective endocarditis by Wilson and associates (2007) in *Circulation* represents a major change. The American Heart Association originally published guidelines for infective endocarditis prevention in 1955. Before the 2007 update, the last changes were in 1997. Since that time, the efficacy of antimicrobial prophylaxis to prevent infective endocarditis in patients undergoing dental, gastrointestinal, and genitourinary procedures has been questioned by many groups. Those seeking further discussion beyond that presented here are referred to the American Heart Association guideline.

Major changes in the guidelines include the following:

- Emphasizes that most cases of infective endocarditis are caused by random bacteremia related to daily exposures, such as chewing, tooth brushing, flossing, and use of toothpicks.
- Review of the literature shows that prophylaxis prevents a very small number of cases of infective endocarditis.
- The risk of antibiotic-associated adverse events appears to exceed the benefit of prophylactic antibiotic therapy, which seems to be very small.
- Current recommendations are based on consideration of those conditions that are most likely to have an adverse outcome from infective endocarditis, not necessarily those with the highest lifetime risk of acquiring infective endocarditis.
- Although the committee acknowledges that there is no convincing evidence that prophylaxis is effective, prophylaxis is considered reasonable for those with the highest risk of adverse outcomes from infective endocarditis.
- Mitral valve prolapse, which is the most common underlying condition that might predispose to infective endocarditis, is not on the list of recommended conditions for prophylactic antibiotic use because the absolute incidence of infective endocarditis in this population is very low, and poor outcomes are extremely uncommon.

Box 221-1 lists the *conditions that are at highest* risk for poor outcomes with infective endocarditis and should therefore be considered for prophylaxis with antibiotics for some procedures. No other cardiac conditions should be considered for prophylaxis for any dental, gastrointestinal, or genitourinary procedures.

Prior recommendations separated *dental procedures* into those for which prophylaxis was or was not recommended, based on risk of bacteremia and subsequent development of infective endocarditis. The updated recommendations indicate prophylaxis for any dental procedure that might involve manipulation of the gingival tissues or apical region of the teeth or perforation of the oral mucosa, including teeth cleaning, only for those at high risk (see Box 221-1). Box 221-2 lists dental procedures for which antibiotic prophylaxis is *not* recommended for anyone.

For those undergoing incision or biopsy of the *respiratory mucosa*, such as tonsillectomy or adenoidectomy, prophylaxis for infective endocarditis with antibiotics is recommended for those with the cardiac conditions at highest risk for poor outcomes (see Box 221-1). This recommendation is in spite of a lack of conclusive data linking respiratory tract procedures to infective endocarditis.

In contrast to prior American Heart Association guidelines, prophylaxis for infective endocarditis is not recommended for gastro-intestinal or genitourinary procedures, including diagnostic esophagogastroduodenoscopy or colonoscopy with or without biopsy. The only exception to this guideline is for those patients with cardiac conditions at highest risk for poor outcomes who have an enterococal urinary tract infection or colonization at the time of a genitourinary procedure. The new guidelines reaffirm that vaginal hysterectomy, vaginal delivery, cesarean section, dilation and curettage, therapeutic abortion, insertion of an intrauterine device, and sterilization procedures do not need prophylactic antibiotics in anyone.

Antibiotic prophylaxis for infective endocarditis for *routine skin* procedures is not recommended. For surgical procedures involving infected skin, skin structures, or musculoskeletal tissue, antibiotic choice should be active against staphylococci and beta-hemolytic streptococci but again, only for those patients listed in Box 221-1.

### Box 221-1. Cardiac Conditions with High Risk of Adverse Outcome

Prosthetic cardiac valve

Previous infectious endocarditis

Congenital heart disease including only the following:

- Unrepaired cyanotic congenital heart disease
- Palliative shunts and conduits
- Completely repaired congenital heart defect with prosthetic material or device (placed surgically or by catheter) during first 6 months after procedure (until endothelialization of prosthetic material occurs)
- Repaired congenital heart disease with residual defects at site of prosthetic patch or device (because endothelialization may be inhibited)

Cardiac transplant recipients with cardiac valvulopathy

A guideline from the American Heart Association Rheumatic Fever, Endocarditis, and Kawasaki Disease Committee, Council on Cardiovascular Disease in the Young, and the Council on Clinical Cardiology, Council on Cardiovascular Surgery and Anesthesia, and the Quality of Care and Outcomes Research Interdisciplinary Working Group. Circulation 116:1736–1754, 2007.

#### Box 221-2. Dental Procedures for Which Antibiotic Prophylaxis Is Not Recommended

Adjustment of orthodontic appliances Bleeding from trauma to the lips or oral mucosa Dental radiographs

Placement of orthodontic brackets

Placement of removable prosthodontic or orthodontic appliances

Routine anesthetic injection through noninfected tissue Shedding of deciduous teeth

Adapted from Wilson W, Taubert KA, Gewitz M, et al: Prevention of infective endocarditis: Guidelines from the American Heart Association. A guideline from the American Heart Association Rheumatic Fever, Endocarditis, and Kawasaki Disease Committee, Council on Cardiovascular Disease in the Young, and the Council on Clinical Cardiology, Council on Cardiovascular Surgery and Anesthesia, and the Quality of Care and Outcomes Research Interdisciplinary Working Group. Circulation 116:1736–1754, 2007.

The new American Heart Association guidelines not only simplify the decision-making process for physicians regarding who should or should not receive antibiotic prophylaxis for infective endocarditis, they shift the emphasis to improved dental care and oral health to decrease routine exposure to bacteremia from oral microflora related to daily activities, which likely cause the vast majority of cases of infective endocarditis.

Figure 221-1 illustrates an approach to appropriate antibiotic selection for those high-risk individuals undergoing a procedure for which prophylaxis for infective endocarditis is indicated. Table 221-1 indicates appropriate doses for adults and children of selected antibiotics used for prophylaxis.

#### WOUND PROPHYLAXIS

Also see Chapter 222, Prevention and Treatment of Wound Infections.

Although antibiotic prophylaxis can reduce wound infection, the benefits must be weighed against the risks of toxic and allergic reactions, selecting for resistant bacteria, drug interactions, and possibly unnecessarily increasing the costs of health care. Prophylaxis is generally recommended only when prosthetic materials are involved, for patients in whom infection can have serious consequence, and in major surgeries. The 2006 reference from *The Medical Letter* reviews current recommendations for prophylaxis.

Patients with *prosthetic joints* generally do not require antimicrobial prophylaxis even for dental, gastrointestinal (GI), or genitourinary (GU) procedures.

For most elective dermatologic and plastic surgeries, antibiotic prophylaxis for wound infection is not routinely indicated unless the procedure is expected to last more than 3 hours or the patient is at high risk for wound infection. Patients at high risk include those with diabetes mellitus, significant obesity, immunosuppression, vascular insufficiency, malnutrition, chronic steroid use, and lymphedema, as well as older patients, among others. It is best to give the antibiotic 1 hour before surgery, but there are benefits to administration even up to 4 hours later. There is no benefit to extending prophylactic therapy beyond 24 to 48 hours. For most procedures, cefazolin, which is effective against streptococci and staphylococci, is an effective and narrow-spectrum choice. However, any antibiotic effective against streptococci and staphylococci, such as erythromycin, may be used. For office surgeries in which prophylaxis is desired, also consider cephalexin and drugs effective against methicillin-resistant Staphylococcus.

Wound care is an important part of a busy outpatient and office practice. For dirty, traumatic wounds, copious irrigation is the most important means of decreasing the incidence of wound infection. Smaller, low-risk wounds and those in more vascular areas usually require less volume, but in most cases the best approach is to follow the dictum: "The solution to pollution is dilution." Irrigation with

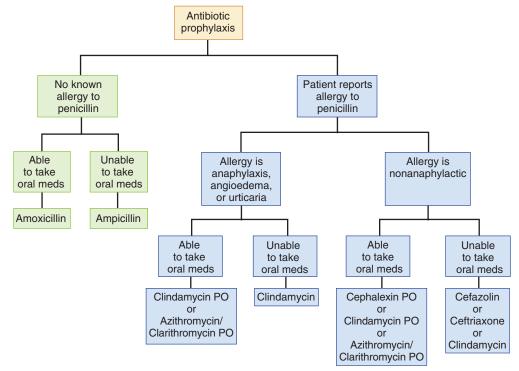

Figure 221-I Appropriate antibiotic selection for high-risk individuals undergoing a procedure for which prophylaxis for infective endocarditis is indicated. PO, orally.

TABLE 221-1 Antibiotic Doses for Prophylaxis of Infective Endocarditis					
Antibiotic	Adult Oral Dose	Pediatric Oral Dose	Adult IV/IM* Dose	Pediatric IV/IM* Dose	
Amoxicillin Ampicillin Cefazolin Ceftriaxone Cephalexin Clindamycin Azithromycin or clarithromycin	2 g N/A N/A N/A 2 g 600 mg 500 mg	50 mg/kg N/A N/A N/A 50 mg/kg 20 mg/kg 15 mg/kg	N/A 2 g 1 g 1 g N/A 600 mg N/A	N/A 50 mg/kg 50 mg/kg 50 mg/kg N/A 20 mg/kg N/A	

IM, intramuscular; IV, intravenous; N/A, not applicable.

Adapted from Wilson W, Taubert KA, Gewitz M, et al: Prevention of infective endocarditis: Guidelines from the American Heart Association. A guideline from the American Heart Association Rheumatic Fever, Endocarditis, and Kawasaki Disease Committee, Council on Cardiovascular Disease in the Young, and the Council on Clinical Cardiology, Council on Cardiovascular Surgery and Anesthesia, and the Quality of Care and Outcomes Research Interdisciplinary Working Group. Circulation 116:1736–1754, 2007.

normal saline is recommended (and warmed saline offers the additional benefit of increased patient comfort over room-temperature solution), but tap water may be an acceptable alternative in nonbite wounds. Povidone—iodine (Betadine) surgical scrub solution, and other antiseptic solutions such as hydrogen peroxide, may be toxic to wound tissue and therefore impede healing. A dilute Betadine solution (1:10), however, may be useful for contaminated wounds. Débridement of the wound plays an equally important role in preventing infection because permanently devitalized tissue impairs the wound's ability to resist infection. In situations in which foreign bodies such as particulate matter or bone fragments may be present, exploration with a metal probe and use of radiographs are indicated. Opening the wound further to permit adequate visualization may be necessary in some cases.

The most common bacteria causing wound infections are *Staphylococcus aureus*, group A streptococci, and *Clostridium* species. If significant injury exists, consider cefazolin, if available, 1 to 2 g intravenous (IV) every 8 hours for one to three doses. For less extensive injuries, oral antibiotics that cover these organisms are also acceptable.

For bite wounds in which likely pathogens may also include oral anaerobes, such as Eikenella corrodens (human) or Pasteurella multocida (dog and cat), amoxicillin with clavulanic acid (Augmentin) or ampicillin sulbactam (Unasyn) is recommended. A 7- to 10-day course may be advisable.

A *human bite* wound over the metacarpophalangeal joints in the hand, commonly caused by fist fighting, can be very serious. If it is suspected that the joint capsule has been entered, IV or intramuscular antibiotics may be indicated. Close follow-up is essential.

For other high-risk wounds, such as those obtained in a barnyard, sewer, or meat packing plant, antibiotics are required for 7 to 14 days. Gentamicin and clindamycin IV may be initially needed.

Clean, sterile technique is mandatory in the excision and repair of any wound in the skin. The 11 most common causes of a wound infection may truly be the naso-oral area and the 10 fingers of the operating physician!

Also, see the discussion on wound prophylaxis in Chapter 22, Laceration and Incision Repair. Chapter 145, Intrauterine Device Insertion, discusses the use of antibiotics at the time of device insertion to prevent endomyometritis and pelvic inflammatory disease. Routine use is not recommended.

# PREVENTION AND TREATMENT OF WOUND INFECTIONS

Madelyn Pollock • Farin W. Smith

Infection is one of the possible adverse outcomes of many procedures. Generally, infection rates in the controlled environment of an office procedure are low and prophylactic antibiotic use is usually not indicated. The rate of infection in traumatic wounds is somewhat higher. Physicians must decide whether to use prophylactic antibiotics in managing surgical or traumatic wounds. Making the right choice involves evaluating the wound, the patient, and the risk—benefit balance. Much of the information available in making that choice is based on opinion, with little being evidence based.

INITIAL WOUND MANAGEMENT

After ensuring that the patient is medically stable, treatment of any wound should begin with hemostasis and a thorough physical examination, with particular attention to motor, sensory, and vascular components. The wound should be anesthetized and copiously irrigated, and any devitalized tissue should be débrided. Use a 30-mL syringe with a large-bore needle (16 to 18 gauge), with a steady, firm force. For large wounds, use at least 500 mL of fluid. A quick method is to hook up a three-way stopcock to a bag of saline. Clean wounds do not need irrigation. However, if there is significant manipulation of a wound (e.g., difficult removal of a deep lesion) or if a cyst has been ruptured during removal, irrigation will help remove small pieces of adipose or cystic contents. In the Cochrane Review "Water for Wound Cleansing" (Fernandez and Griffiths, 2008), tap water is determined to be as safe as sterile water or saline for this irrigation. If the possibility of a retained foreign body exists, a radiograph should be considered (see Chapter 22, Laceration and Incision Repair, for more details). Most wounds can be closed for up to 12 hours from the time of injury. The American College of Emergency Physicians (ACEP) guidelines recommend no more than 8 to 10 hours from injury to closure and less time (6 hours or less is optimal) for wounds of the hands and feet; however, clinical judgment may allow the time in the lowest-risk wounds to extend up to 20 hours. Clean superficial wounds on the head and neck can be safely closed for up to 12 hours or longer in healthy patients. Grossly contaminated wounds and most wounds older than 12 hours should be allowed to heal by secondary intention or undergo delayed closure in 4 to 5 days. Puncture wounds should not be closed. Buried absorbable subcutaneous sutures increase the infection rate in irrigated contaminated wounds and should be avoided. Shaving of wound sites should be avoided if possible because it increases the likelihood of infection.

#### **PATIENT FACTORS**

Certain patient or wound characteristics are associated with a possible increase in wound infection. When these higher-risk situations apply, there is little evidence to guide the practitioner's decision to

use or not use prophylaxis. Conditions to consider are listed in Box 222-1. All of these conditions or characteristics can increase the risk of infection. The use of the antibiotic itself carries the risk of allergic reactions, development of resistant organisms, antibiotic-associated colitis, fungal superinfections, and increased costs to the medical system. A careful assessment of risk and potential benefit should be made before making the choice.

# Box 222-1. When to Consider Antibiotic Prophylaxis for Surgical and Traumatic Wounds

#### **Comorbid Conditions**

- Diabetes mellitus
- Peripheral vascular disease (if wound on extremity involved)
- Elderly
- Immunocompromised
- · History of radiation to site of wound
- Malnutrition (e.g., alcoholic, chemotherapy, chronic debility)
- History of previous wound infection or slow healing
- Chronic steroid use
- Obesity
- Pedal edema with leg wounds
- History of poor healing
- Collagen vascular diseases

#### Wound Locations and Characteristics

- Increased bacteria—axilla, inguinal fold, mouth, anogenital area
- Over joint spaces where invasion of space possible (finger and toe joints in particular)
- Residual devitalized tissue (should be rare)
- Penetrating injury, particularly if mucous membrane perforation possible
- Stellate wounds
- Wounds deeper than the subcutaneous tissue

#### Contamination

- Dirty wounds, particularly if contaminated with feces, meat, seawater
- Break in sterile technique
- Deep puncture wounds
- Bites (human and cat; <5% of dog bites result in infection)
- Presence of residual foreign body

#### **WOUND FACTORS**

#### Prophylaxis in Clean Surgical Wounds

The use of prophylactic antimicrobials is *not* indicated in the vast majority of dermatologic procedures. In certain patient types and in some wound locations, antimicrobial prophylaxis may be indicated (see Box 222-1). If an antibiotic is indicated, the most common regimen for adults is a first-generation cephalosporin in a dose of 1 g given orally. Clindamycin 300 mg orally is the alternative for allergic patients. The dose should be given at least 30 minutes but not longer than 1 hour before the incision in clean, scheduled cases. This timing is important. Efficacy decreases with doses given earlier or later.

Topical application of antibiotic ointment has been shown to decrease wound infections better than petrolatum alone. Mupirocin applied after clean procedures was not more effective than commonly available triple-antibiotic ointment in preventing infection and is much more expensive. A generic mupirocin ointment (not cream) has become available and is somewhat less expensive. Because of risk of hypersensitivity, topical neomycin should be avoided if possible. Neomycin is present in most generic triple-antibiotic formulations and in Neosporin; it is not present in Polysporin or Bacitracin. If a patient complains of redness and itching, and is using a neomycin product (or some other topical antibiotic), the clinician should suspect allergy, rather than a resistant organism and infection.

#### **Prophylaxis in Traumatic Wounds**

Prophylactic antimicrobials in traumatic wounds are those used within 24 hours of the event and before there is evidence of infection. Their use is not indicated in the vast majority of traumatic wounds in healthy patients. Copious and thorough wound irrigation is the most important intervention to prevent infection. When risks are particularly high, either because of patient factors or wound characteristics, prophylactic antibiotics may be used. First-generation cephalosporins are the drugs of choice. Injuries associated with contamination from saliva, blood, feces, meat, and seawater are more likely to become infected. However, there is no clear indication for antibiotics versus copious irrigation and early treatment for signs of infection (Table 222-1).

#### Rabies Prophylaxis in Animal Bites

The Cochrane Database (Medeiros and Saconato, 2001) reports that there is good evidence to support routine use of prophylactic antibiotics in wounds from *cat and human* bites because these are

likely to get infected even when copiously irrigated (see Table 222-1). Blunt trauma resulting from contact with the human mouth (e.g., a punch to the face) should be treated as a human bite if the skin is broken. Dog bites tend to become infected less than 5% of the time. Ampicillin–clavulanate is the recommended antibiotic for prophylaxis in bite wounds. Rabies should always be a consideration when treating patients with animal bites. The animal's location and rabies vaccination status should be assessed and the local public health department should be contacted. Decisions regarding post-exposure rabies prophylaxis are complex and depend on the animal involved, the degree of contact, local epidemiology, and the results of testing, when available. In most states a period of observation is required and rabies prophylaxis can be delayed unless and until the offending animal exhibits clinical signs of infection.

#### TREATMENT OF WOUND INFECTIONS

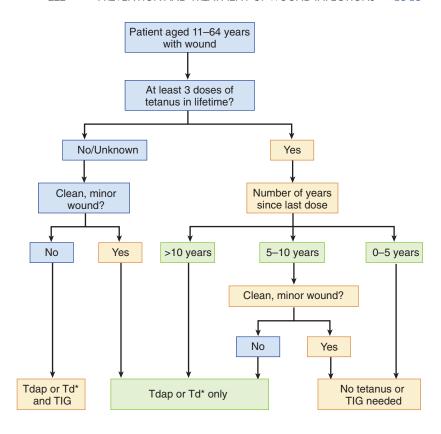

Patients should always be educated about the signs and symptoms of wound infection after a procedure and asked to return for early evaluation should the classic signs of redness, swelling, warmth, increased pain, or purulent drainage occur. An early postoperative evaluation of the wound at 48 to 72 hours might be useful in patients at high risk of infection. If infection is detected, extraction of some or all suture material with irrigation and exploration of the wound may be indicated if there is no marked improvement in 24 hours with antibiotics. Devitalized or obviously infected tissue should be débrided. A Gram stain and culture of the wound should guide the choice of antibiotic therapy.

The most common organisms present are staphylococci or streptococci. More often in recent years, methicillin-resistant Staphylococcus aureus is the culprit. Therefore, trimethoprim/ sulfamethoxazole preparations are now recommended as first-line therapy, replacing cephalexin or other first-generation cephalosporins. It is important to be guided by resistance profiles in your area. Clindamycin is recommended for allergic patients. In the specific setting of bite wounds, ampicillin-clavulanate is recommended as first-line therapy if not used as a prophylactic antibiotic. For cat bites, the most common cause of infection is Pasteurella multocida. which has a high rate of resistance to dicloxacillin and cephalexin; therefore, these should not be used. As an alternative to systemic antibiotics, topical mupirocin has been shown to perform as well as systemic cephalosporins in treating uncomplicated surgical skin infections. In wounds close to bony structures, osteomyelitis should be considered when the response is not prompt, and consideration given to ciprofloxacin.

TABLE 222-1 Choice of Antibiotic Prophylaxis when Indicated						
Setting	Recommendation	Comments				
Adult bites (or child >40 kg) with wound from human mouth contact (bite or punch)	Ampicillin–clavulanate 875/125 mg PO every 12 hr for 3–5 days	Even small skin breaks should receive prophylaxis because infection rates are high.  Hand wounds are especially worrisome if over joint spaces.				
Child bites (>3 mo and <40 kg) with hand wound from human mouth contact (bite or punch)	First dose parenteral: ampicillin-sulbactam 50 mg/kg of ampicillin to max. 3 g; then 45 mg/kg/day divided every 12 hr for 3–5 days	Alternative is clindamycin 5–10 mg/kg IV to max. of 600 mg, then PO clindamycin 10–30 mg/kg/day PO divided every 6–8 hr, plus trimethoprim/sulfamethoxazole 8–10 mg/kg/day of trimethoprim divided every 12 hr for 3–5 days.				
Dog bites, low risk	No antibiotics in healthy patients	Infection rate <5% if wound well irrigated.				
Dog bites, high risk, and cat bites	Same as above for human bite	High-risk dog bites include hand bites, deep punctures.				
Wounds sustained in seawater or in wet/dirty environments (e.g., plumber)	Tetracycline	Vibrio species often the organism; treat based on culture when possible.				
Intraoral wounds, full thickness or "through-and-through" in adults	Penicillin VK 500 mg every 6 hr for 5 days or Clindamycin I 50–450 mg PO every 6 hr for 5 days	Increased rate of infection if sutures used.				
Most surgical wounds, clean		Copious irrigation recommended for most traumatic wounds.				
Surgical wounds when risk factors present (see Box 222-1)	First-generation cephalosporin I g PO 30–60 min before procedure	If allergic, clindamycin 300 mg PO.				
Surgical wounds when risk factors	First-generation cephalosporin I g PO 30–60 min	,				

IV, intravenous; PO, oral.

Figure 222-I Tetanus prophylaxis decision tree. A wound does not qualify as a "clean, minor wound" if it is contaminated with dirt, feces, soil, or saliva; is a puncture wound or avulsion; or is a wound resulting from missiles, crushing, burns, or frostbite. Td, tetanus and diphtheria toxoids vaccine; Tdap, tetanus toxoid, reduced diphtheria toxoid, and acellular pertussis vaccine; TIG, tetanus immunoglobulin; TT, tetanus toxoid, \*Tdap is preferred to Td for adults or adolescents who have never received Tdap. Td is preferred to TT for adults/adolescents who received Tdap previously or when Tdap is not available. If TT and TIG are both used, Tetanus Toxoid Adsorbed rather than tetanus toxoid for booster use only (fluid vaccine) should be used. (From Broder KR, Cortese MM, Iskander JK, et al: Preventing tetanus, diphtheria, and pertussis among adolescents: Use of tetanus toxoid, reduced diphtheria toxoid and acellular pertussis vaccines. Recommendations of the Advisory Committee on Immunization Practices [ACIP]. MMWR Recomm Rep 55[RR-3]: I-34, 2006; and Kretsinger K, Broder KR, Cortese MM, et al: Preventing tetanus, diphtheria, and pertussis among adults: Use of tetanus toxoid, reduced diphtheria toxoid and acellular pertussis vaccine. Recommendations of the Advisory Committee on Immunization Practices [ACIP] and recommendation of ACIP, supported by the Healthcare Infection Control Practices Advisory Committee [HICPAC], for use of Tdap among health-care personnel. MMWR Recomm Rep 55[RR-17]:1-33, 2006.)

#### **Seawater Wounds**

For the special circumstances of wounds associated with exposure to seawater, and the possibility of infection with *Vibrio* species, tetracycline has been shown to be the drug of choice, but many other choices are effective. Treatment should be based on culture when possible.

#### **TETANUS PROPHYLAXIS**

An important, and too often overlooked, aspect of wound management is tetanus prophylaxis. It is easy to overlook in atypical wounds, such as foreign bodies in the eye or superficial burns. All wounds that penetrate the superficial skin should be considered for tetanus prophylaxis based on immunization history and type of wound (Fig. 222-1). The recent release of the tetanus toxoid, reduced diphtheria toxoid, and acellular pertussis (Tdap) vaccines Boostrix and Adacel has changed the Centers for Disease Control and Prevention (CDC) recommendations for use of tetanus in adults and adolescents (Table 222-2). Of note, for individuals with an unknown number or less than three tetanus-containing immunizations before the injury, the CDC recommends use of tetanus immunoglobulin (TIG) for all but "clean, small" wounds. These guidelines do not use age of wound, mechanism of injury, or presence of devitalized tissue to distinguish between wounds that might be an indication for TIG and those that are not.

#### **CPT/BILLING CODES**

The postoperative management of wound infections usually will be included in the initial charge for the wound management or operative procedure if it occurs within 10 days ("10-day global period"). If the treatment of the infection is complex, the following code can be used:

10180 Incision and drainage of complex postoperative wound infection

**TABLE 222-2** Guide to Tetanus Prophylaxis in Routine Wound Management among Adults and Adolescents Aged 11 to 64 Years

History of Tetanus	Clean, Minor Wound		All Other Wounds*		
Doses	Tdap or Td <sup>†</sup>	TIG	Tdap or Td <sup>†</sup>	TIG	
Unknown or <3 ≥3	Yes No <sup>‡</sup>	No No	Yes No <sup>§</sup>	Yes No	

Tdap, tetanus toxoid, reduced diphtheria toxoid, and acellular pertussis vaccine; Td, tetanus and diphtheria toxoids vaccine; TlG, tetanus immunoglobulin; TT, tetanus toxoid.

\*Such as, but not limited to, wounds contaminated with dirt, feces, soil, and saliva; puncture wounds; avulsions; and wounds resulting from missiles, crushing, burns, and frostbite.

<sup>†</sup>Tdap is preferred to Td for adults or adolescents who have never received Tdap. Td is preferred to TT for adults or adolescents who received Tdap previously or when Tdap is not available. If TT and TIG are both used, Tetanus Toxoid Adsorbed rather than tetanus toxoid for booster use only (fluid vaccine) should be used.

 $^{\ddagger}$ Yes, if  $\geq$ 10 years since the last tetanus toxoid—containing vaccine dose.

§Yes, if ≥5 years since the last tetanus toxoid-containing vaccine dose.

From Broder KR, Cortese MM, Iskander JK, et al: Preventing tetanus, diphtheria, and pertussis among adolescents: Use of tetanus toxiod, reduced diphtheria toxoid and acellular pertussis vaccines. Recommendations of the Advisory Committee on Immunization Practices (ACIP). MMWR Recomm Rep 55(RR-3): I–34, 2006; and Kretsinger K, Broder KR, Cortese MM, et al: Preventing tetanus, diphtheria, and pertussis among adults: Use of tetanus toxoid, reduced diphtheria toxoid and acellular pertussis vaccine. Recommendations of the Advisory Committee on Immunization Practices (ACIP) and recommendation of ACIP, supported by the Healthcare Infection Control Practices Advisory Committee (HICPAC), for use of Tdap among health-care personnel. MMWR Recomm Rep 55(RR-17): I–33, 2006.

Other codes that may be useful in certain situations include the following:

- 12020 Treatment of superficial wound dehiscence, simple closure
- 12021 Treatment of superficial wound dehiscence with packing
- 13160 Secondary closure of surgical wound or dehiscence, extensive or complicated

#### **ICD-9-CM DIAGNOSTIC CODES**

- NOTE: Always include date of injury and measurement of wound.
- 027.2 Infection by *Pasteurella multocida* including septic infection (cat or dog bite)
- 958.3 Post-traumatic wound infection, not elsewhere classified Excludes: infected open wounds—code to complicated open wound of site
- 998.3 Disruption, dehiscence, or rupture of operation wound 998.5 Postoperative infection
- Excludes: infection due to implanted device or postoperative obstetric wound

# **BODY FAT ANALYSIS**

Russell D. White • Darrin Ashbrooks

Body fat analysis is a quantitative method for assessing obesity and lean body mass. Several methods of body fat analysis are listed in Table 223-1, and each has advantages and disadvantages. Body fat analysis is more accurate than using body mass index (BMI) for evaluation.

Traditional methods such as densitometry and skin-fold measurements are based on the two-compartment model (fat and fat-free mass). Densitometry (underwater weighing) is cumbersome and not readily available. Alternative methods include dual energy x-ray absorptiometry (DEXA) and total-body electrical conductivity (TOBEC), which distinguish four compartments (water, protein, fat, and bone). Imaging techniques such as computed tomography (CT) scanning and magnetic resonance imaging (MRI) also can give estimates of subcutaneous and visceral fat. Although some of these methods are impractical and require expensive and bulky instruments, several methods can be performed quickly and easily in the office setting. These include skin-fold measurements, bioelectrical impedance, and infrared interactance.

#### **INDICATIONS**

- Assessment of conditioning or fitness level
- Assessment of nutritional status
- Obesity
- Risk stratification for disease states (e.g., hypertension, diabetes, coronary artery disease)

#### **CONTRAINDICATIONS**

- Patient refusal
- For MRI, patients with pacemakers, implantable defibrillators, spinal cord stimulators, or implantable pain pumps
- For bioelectrical impedance, caution in patients with implantable defibrillators or pacemakers

#### **SKIN-FOLD MEASUREMENTS**

In the outpatient setting the most widely used method is the measurement of skin-fold thickness in various predetermined sites.

#### **Equipment**

- Marking pen (optional)
- Measuring tape (optional)
- Skin-fold calipers (Fig. 223-1)

#### **Technique**

- Although it matters little on which side of the body measurements are taken, by convention, measurements are taken on the right side.
- 2. Measure the exact same sites for serial comparisons.

- 3. Be familiar with the skin-fold site to be measured, and pull the skin fold once or twice before the actual measurement.
- 4. Grasp the skin fold with the index finger and thumb of one hand and pull a fold away from the body with the sides approximately parallel. Asking the patient to contract the underlying muscle will help in grasping only skin and fat.
- 5. Place the caliper heads approximately 0.5 cm away from the fingers holding the skin fold. Place the caliper heads perpendicular to the skin fold and measure 4 to 5 seconds after releasing the lever arm of the calipers.
- Maintain constant pressure with the thumb and index finger throughout the measurement.
- Take a minimum of two measurements 15 seconds apart at each site until consecutive measurements vary by no more than 1 mm, to ensure consistency.
- 8. Measuring obese subjects may require both hands to pull a skin fold away with parallel sides. In this case, an assistant is needed to place the caliper heads on the skin fold.
- 9. Take measurements when the skin is dry and when the subject is not overheated (e.g., after exercise). Vasodilation of the skin in these conditions will inflate normal skin-fold size.
- 10. Proficiency and accuracy require practice.

Measurements at seven common sites are described as follows:

- 1. *Chest:* Pick up the pectoral skin fold at the anterior axillary line with the long axis directed to the nipple. Place the skin-fold calipers approximately 2 cm anterior to the anterior axillary line (Fig. 223-2).
- Subscapular: Lift a diagonal fold parallel to the medial border of the scapula at a point just below the inferior angle of the scapula (Fig. 223-3).
- 3. Triceps: Pick up a vertical fold on the posterior arm 1 cm above the midway point between the lateral edge of the acromion and

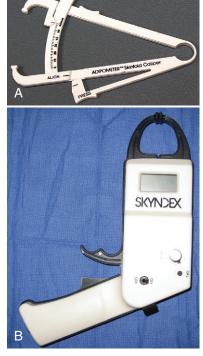

Figure 223-I A and B, Skin-fold calipers.

the inferior border of the olecranon. A measuring tape may be helpful in determining the midpoint (Fig. 223-4). Measurements are taken with the arm hanging loosely at the side and with the caliper heads placed precisely at the midpoint (Fig. 223-5).

- 4. Abdomen: Pick up a horizontal fold 3 cm lateral to and 1 cm below the navel (Fig. 223-6).
- 5. Suprailiac: Pick up a diagonal fold along Langer's lines above the iliac crest just posterior to the mid-axillary line, with the calipers placed approximately 1 cm anterior to the grasping fingers. The arm should hang naturally to the side but can be moved slightly to improve access (Fig. 223-7).
- 6. Thigh: Measure a vertical fold midway between the inguinal crease and the superior border of the patella. It may be helpful to use a measuring tape to determine the midpoint of the anterior thigh (Fig. 223-8). Pick up the skin fold 1 cm above this point. The subject should have his or her body weight shifted to the opposite side, with the measured leg in slight knee flexion and the foot flat on the floor (Fig. 223-9).
- 7. Medial calf: Measure a vertical fold at the level of the maximum calf circumference on the medial side of the calf. The measured leg should not bear weight and can be measured with the patient in either the standing or the seated position (Fig. 223-10).

#### **Calculations**

Numerous regression equations with various anthropometric measurements have been used to calculate body fat percentage. However, the following equations by the American Alliance for Health, Physical Education, Recreation, and Dance (AAHPERD), used in children and youth (6 to 17 years of age), and those developed by Jackson and Pollock for adults are among the most widely used and accepted.

- For children and youth, a two-site skin-fold test is done, using the triceps and medial calf sites:
  - Boys 6 to 17 years: % body fat = (0.735 × Sum of skin folds in mm) + 1.0
  - Girls 6 to 17 years: % body fat = (0.610 × Sum of skin folds in mm) + 5.0
- For adults, the three-site equations developed by Jackson and Pollock are as follows:
  - Men: Body density = 1.1093800 0.0008267(x) + 0.0000016(x)<sup>2</sup> 0.0002574(Age)
    - where x = sum of chest, abdomen, and thigh skin folds in mm % body fat = (495/Body density) 450
    - % body fat =  $0.39287(x) 0.00105(x)^2 + 0.15772(Age) 5.18845$
    - where x = sum of abdomen, suprailiac, and triceps skin folds in mm
  - Women: Body density =  $1.0994921 0.0009929(x) + 0.0000023(x)^2 0.0001392(Age)$ 
    - where x = sum of triceps, suprailiac, and thigh skin folds in mm
    - % body fat = (495/Body density) 450
    - % body fat =  $0.41563(x) 0.00112(x)^2 + 0.03661(Age) + 4.03653$

**Figure 223-8** Determining the midpoint of the anterior thigh between the inguinal crease and the superior border of the patella.

Figure 223-9 Measurement of the thigh skin fold.

where x = sum of triceps, abdomen, and suprailiac skin folds in mm

Other formulas have been used, such as those developed by Durnin and Womersley. Also, many clinicians have found the nomogram from AAHPERD useful for determining body fat percentage (Fig. 223-11). Table 223-2 shows weight classifications for men and women.

#### **BIOELECTRICAL IMPEDANCE**

Bioelectrical impedance is based on differences in electrical conductivity through tissue depending on the amount of fat-free mass. A greater percentage of fat-free mass increases electrical conductivity, which decreases impedance. Mass is measured by applying an electrode to one leg and one arm or by standing on the foot plate of a special scale. A variety of formulas have been developed to convert the impedance, which measures body water, into an estimate of body fat.

#### **Equipment**

- Bioelectrical impedance measuring device (Fig. 223-12A)
- Foot plate of special scale (Fig. 223-12B)

#### **Technique A**

See Figure 223-12C and D.

**Figure 223-12 A,** Bioelectrical impedance measuring device. **B,** Foot plate of special scale. **C** and **D,** Electrodes are placed on the right hand and right foot. (Courtesy of Biodynamics Corp., Seattle, Wash.)

 Electrical conductance (or impedance) is measured and percentage lean body mass is subsequently automatically calculated by the machine.

#### Technique B

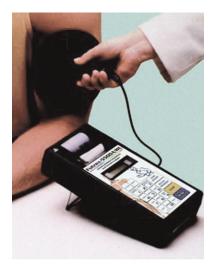

- 1. Have the subject follow the guidelines given in step 1 of technique A.
- 2. Have the subject stand in limited clothing on the foot plate of a special scale (see Fig. 223-12B).
- Electrical conductance (or impedance) is measured and percentage lean body mass is subsequently automatically calculated by the instrument.

#### **Complications**

Bioelectrical impedance should not be used in patients with implantable defibrillators or pacemakers.

#### **NEAR-INFRARED INTERACTANCE**

Near-infrared interactance (NIR) is based on the principles of light absorption and reflection and uses near-infrared spectroscopy. The degree of infrared energy absorption is related to the composition of the substance through which the energy is passing and the particular wavelength of the energy. Hence, lean body mass and fat can be distinguished from each other and a percentage calculated.

**Figure 223-13** Measurement using computerized, near-infrared spectrophotometer with fiberoptic probe. (Courtesy of Futrex, Inc., Gaithersburg, Md.)

# **Equipment**

A computerized, near-infrared spectrophotometer with fiberoptic probe, practical for office use (Fig. 223-13), is necessary.

# **Technique**

The fiberoptic probe commonly is placed over the belly of the biceps muscle to gather the near-infrared data. Specific requirements, including anatomic location for probe placement, may differ depending on the individual spectrophotometer (see Fig. 223-13).

# **Complications**

There are no complications associated with NIR.

# **DUAL-ENERGY X-RAY ABSORPTIOMETRY**

Densitometry has been the gold standard for determining body fat. However, this technique has now been replaced by dual energy x-ray absorptiometry (DEXA) because of its ease of use.

**NOTE:** There have been questions regarding DEXA's accuracy in child and adolescent models. Compared with other methods, DEXA overestimated body fatness at lower values. It has been recommended that this method not be used for calibration of field methods in the pediatric population.

DEXA estimates lean mass, body fat, and bone mineral density by using the differential absorption of photon beams of two levels of intensity. DEXA relies on the principle that the intensity of a photon beam is altered by the thickness, density, and chemical composition of an object in its path. In children, the scan takes approximately 10 minutes. The average radiation dose is barely higher than normal background radiation, and well below that of a chest radiograph.

# **Equipment**

A DEXA scanner is required.

# **Complications**

Although it is minimal, there is radiation exposure. DEXA is contraindicated in the first trimester of pregnancy and relatively contraindicated in the second and third trimesters.

# MAGNETIC RESONANCE IMAGING AND COMPUTED TOMOGRAPHY SCANS

Regional body fat distribution can be determined reliably by either CT or MRI scan. CT uses x-radiation and computer analysis to determine the structure of internal organs. It is possible to obtain an accuracy within less than a 1% margin of error for body fat using a series of scans. With MRI the patient is placed in an electromagnetic field that creates tissue (body) images. Hydrogenated (1H) atoms possess an unpaired proton and exhibit a spin that results in a magnet moment. <sup>1</sup>H atoms react to an external magnetic field when radiowaves are pulsed to a patient at a specific frequency and are absorbed by the nuclei. Fatty tissue is high signal on T1-weighted images, while fluid (water) is high signal on T2-weighted images. In addition, fat suppression techniques that cause fat to lose signal or become dark while fluid stays bright or high signal are available. The ratio of whole body fat/nonfat tissue can be determined because the human body is primarily fat and water. MRI takes longer to perform than CT and is considerably more expensive.

# **Equipment**

An MRI or CT scanner is necessary.

# **Technique**

These scans are used mainly for analysis of body fat in a certain region, most commonly the abdomen. There are different methods of CT scanning, but the most common is to take a single cut through the L4-5 position and compute the regional body fat percentage from this cut. This method minimizes the patient's exposure to radiation. Likewise, MRI methods usually consist of scanning a region such as the abdomen and computing data from this region.

# **Complications**

There is moderate radiation exposure with CT scans and they are relatively contraindicated in pregnancy. MRI is contraindicated in patients with pacemakers, implantable defibrillators, and intracranial metal clips (until 8 weeks after CNS surgery) or following documentation of material utilized in the procedure. After implantation, patients are issued a medical card indicating whether MRI is acceptable. Since 1995, new materials have been used for pacers and defibrillators, and many are now acceptable.

# **BOD POD**

BOD POD (Air Displacement) is based on the same principle as underwater weighing and uses computerized sensors to measure how much air is displaced while a person sits for 20 seconds in a capsule. The BOD POD determines body mass and volume and from these two variables computes body density. From this calculation body fat is determined. The equipment is very expensive and limited in availability. Studies have shown that it is comparable with underwater weighing. There has been some variance in outcomes (–3.0% to 1.7%) when air displacement is compared with other methods, such as DEXA scanning. These differences are likely due in part to differences in laboratory equipment, study design, and subject characteristics, and in some cases to failure to follow the manufacturer's recommended protocol.

# **Equipment**

The BOD POD capsule and associated computerized equipment are required.

# **Technique**

1. The subject should avoid eating or exercising for at least 2 hours before testing.

- 2. The subject removes clothing, jewelry, and eyeglasses and should wear form-fitting clothing (e.g., Spandex or Lycra swimsuit).
- 3. A swim cap is worn to compress air pockets from the hair.
- 4. The subject avoids moving, talking, or laughing.
- 5. During the test, slight pressure changes occur, similar to what is experienced in a moving elevator.

# NC-STAT NERVE CONDUCTION TESTING

Thomas A. Kintanar

The NC-stat System (NeuroMetrix, Inc., Waltham, Mass) is designed to perform standard noninvasive nerve conduction studies. The system has three components that work together to accurately and rapidly evaluate peripheral nerve function. This enables physicians to manage patient care more effectively and efficiently—all within the office or clinic setting. This diagnostic tool has the capability of approximating the results of more invasive electromyographic (EMG) testing, but with the purported advantage of patient comfort without sacrificing diagnostic accuracy. The neural waveform analysis provided is parallel to traditional EMG analysis without the pain conferred by traditional EMG. The unit, connectors, and biosensors are all available from NeuroMetrix.

The NC-stat system is termed an *automated system*, which clearly delineates it from a standard EMG system, which is a manual system. There are some advantages, but also disadvantages, conferred by an automated system. The *advantages* include standardized methods and reference ranges; technical setup can be performed by staff with basic training; the process is rapid and consistent; support systems can aid the clinician with reports to assist in diagnosis; and the procedure is completely automated. The *disadvantages* of this system in deference to traditional needle EMG are that it is limited to nerves for which the system was specifically designed; is less flexible than other systems; is not suitable for children; and may not work well in anatomically challenged patients (e.g., amputees).

# **ANATOMY**

Neurons serve as the primary functional unit of the nervous system. The basis of the evaluation is centered around the basic components of a *neuron*. The components consist of a *cell body* that contains a nucleus and axon (nerve fiber) and creates an electrochemical action potential to stimulate communication with other neurons or muscle fibers; a *dendrite* that receives input from other neurons and transmits the signal to the cell body for interpretation; and the *synapse*, which is the connecting point between a neuron and muscle fiber or two neurons.

Peripheral nerves are a collection of thousands of nerve fibers whose cell bodies are located in either the dorsal root ganglia (sensory neurons) or the anterior horn (motor neurons) of the spinal cord. Nerve fibers can be characterized by the amount of myelin surrounding each axon. Myelin is an insulator that enhances the speed of action potential propagation. Thus, axons can be thinly myelinated (A-delta pain fibers), unmyelinated (temperature and pin prick), or thickly myelinated (motor or sensory fibers that carry vibration, light touch, and proprioception). Thin myelination is considered to be less than 0.5 mm, whereas thick myelination is greater than 1 mm.

# **INDICATIONS**

Indications for NC-stat testing include the EMG diagnosis of the following:

- Polyneuropathies: diabetes, chronic inflammatory demyelinating polyneuropathy (toxic, metabolic, drug-induced polyneuropathy), acute demyelinating polyneuropathy (i.e., Guillain-Barré syndrome)
- Upper extremity neuropathies: carpal tunnel syndrome, cubital tunnel syndrome
- Spine and lower extremity disorders: tarsal tunnel syndrome, spinal stenosis, lumbosacral radiculopathy
- Generalized disorders: myopathy, motor neuron disease, disorders of neuromuscular transmission (e.g., myasthenia gravis)

# **CONTRAINDICATIONS**

# Relative

- Anticoagulation (for the needle examination).
- Check for medication administration (e.g., if patient has myasthenia gravis, medication may alter the validity of the examination).

# **Absolute**

Other than placing a needle through an infected area, there are no absolute contraindications.

# **EQUIPMENT AND SUPPLIES**

# **NC-stat Biosensors**

A biosensor is a preconfigured standard array of electrodes, eliminating the need for placement of multiple needles in very precise locations; multiple sites can be studied instead (Figs. 224-1 to 224-6). The NC-stat biosensor integrates flexible circuitry and a proprietary electrochemical gel with stimulus and sensing electrodes. An embedded chip monitors skin surface temperature, an important covariant for nerve conduction studies. A unique serial number is also embedded in the chip to conveniently link patients to their test results. Currently, biosensors are available for the median, ulnar, cubital, peroneal, sural, and tibial nerves.

# **NC-stat Monitor**

The NC-stat monitor houses sophisticated proprietary technology for conducting accurate nerve conduction studies. The monitor

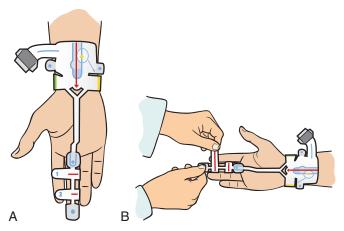

Figure 224-I A and B, Median nerve biosensor.

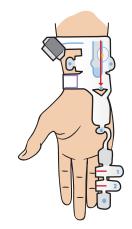

Figure 224-2 Ulnar nerve biosensor.

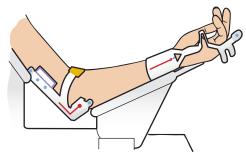

Figure 224-3 Cubital nerve biosensor.

Figure 224-4 Peroneal nerve biosensor.

Figure 224-5 Sural nerve biosensor.

measures standard nerve conduction parameters—amplitude, latency, and conduction velocity—of the motor and sensory nerves. The NC-stat can record the smallest signals for early detection of disease.

A nerve conduction study is initiated with the press of a button. The monitor automatically stimulates the nerve, acquires all the response waveforms, and displays response parameters in real time on the liquid crystal display screen. Using advanced signal processing and control algorithms, the monitor determines stimulation intensity, waveform validity, real-time response parameters, noise artifacts, and appropriate NC-stat biosensor contact.

# **NC-stat Docking Station**

This component receives nerve conduction data and waveforms from the monitor and, at the physician's direction, can automatically transmit the data to the On-Call Information System at NeuroMetrix through any available analog telephone line (such as those used by facsimile machines) in minutes. The monitor can also be remotely upgraded by the docking station, thus ensuring that the system is always up to date with the latest software (Fig. 224-7).

# **On-Call Information System**

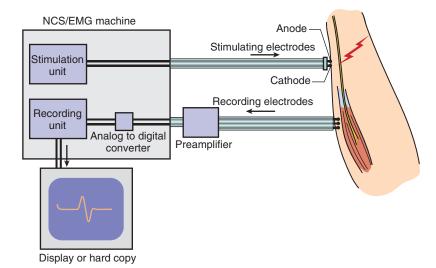

This component at NeuroMetrix receives data from the docking station and automatically generates a report in real time that is returned to the physician within minutes by facsimile or e-mail. The report includes nerve conduction data originally displayed by the monitor, response waveforms, comparison with reference data, and summary data. Nerve conduction data are archived for sequential testing and trending. Suggested interpretation and diagnostic considerations are provided.

# **PRECAUTIONS**

No general precautions are needed, except to remind the patient not to use lotions or oils, which may alter the quality of the signals evaluated. Alcohol wipes are sufficient to remove oils from contact points.

Figure 224-6 Tibial nerve biosensor.

**Figure 224-7** The basic unit of operation in obtaining the recorded data.

# PREPROCEDURE PATIENT EDUCATION AND FORMS

Patient education forms and insurance/Medicare/Medicaid waiver forms are available online at www.neurometrix.com.

# **PROCEDURE**

The bulk of this procedure is performed by ancillary staff. The biosensors are placed by staff who are trained in the proper technique or by the physician/clinician. Proper placement of the biosensors is essential for accurate interpretation of the submitted data (see Figs. 224-1 to 224-6). Instructions for the accurate placement of the leads and operation of the NC-stat module are found online at www.neurometrix.com. Proficiency in the use of the NC-stat system is easily attained. However, it is important to highlight the basic elements of interpretation of the traditional EMG, which correlate with the NC-stat system interpretation. The two major evaluative points of EMG or nerve conduction include (1) evaluation of spontaneous muscle activity performed while the muscle is at rest, and (2) evaluation of voluntary activity performed when the patient is requested to contract the muscle. The oscilloscope findings may demonstrate the muscle electrical potential tracings shown in Figures 224-8 to 224-10.

# SAMPLE OPERATIVE REPORT

A sample operative report is available online at www.neurometrix.com. The clinician uses the initial interpretation along with his or her cognitive knowledge of neural wave patterns and the clinical presentation of the patient to agree with or supplement the initial interpretation, or to synthesize another interpretation germane to the patient.

# **COMPLICATIONS**

- For needle EMG: infection, bleeding, pain
- For NC-stat: none apparent except surface allergies to the biosensors

# POSTPROCEDURE PATIENT EDUCATION

An appointment should be scheduled to review the results with the patient.

# INTERPRETATION OF RESULTS

The basic electrophysiologic assessment of peripheral nerve conduction depends on the response of nerves to electrical stimulation. The study is objective and independent of patient input. It is also quantitative, providing numeric values that can be compared rigorously against reference ranges. The results of a nerve conduction study are reproducible and assess peripheral sensory neurons, motor neurons, and the neuromuscular junction. Nerve conduction studies also document the presence, nature, distribution, and severity of peripheral nerve impairment and have high diagnostic sensitivity and specificity for most types of peripheral nerve disorders.

There are no standard or normative reference ranges used for conduction studies. Each laboratory usually has it own reference range or uses published parameters determined using rigorous clinical study design. Reference values may depend on height, age, and sex. Only reference data that are demographically matched should be used for determining an abnormality. Obviating this detail may lead to poor sensitivity and specificity of resultant data. The basic components of a sensory nerve conduction study starting with baseline at 0 milliseconds are shown in Figure 224-11.

When stimulating the nerve, the stimulus should be strong enough to stimulate all axons in the nerve, which is termed *supramaximal*. A *submaximal* stimulus may lead to inaccurate data being recorded. This potential problem is minimized by the NC-stat technology.

Under the usual needle protocol, a strong, appropriate stimulus is achieved by slowly and gradually increasing the intensity and duration of the stimulus until maximal stimulus is achieved. The NC-stat technology performs this function through its biosensor units. In *motor conduction studies*, the nerve is stimulated at two or more points along its course while the electrical response of one of the muscles supplied is recorded. The muscle response is recorded by surface (biosensors) or subcutaneous needle electrodes, with the

Figure 224-9 Abnormal wave pattern demonstrating positive sharp wave.

Figure 224-8 Normal wave pattern.

**Figure 224-10** Abnormal wave pattern demonstrating fibrillation potential.

active electrode being placed over the end-plate region and the reference electrode over the muscle tendon. The response recorded is called the *compound muscle action potential (CMAP)*, or M wave, and it represents the sum of the electrical activity of all the activated muscle fibers within the pickup region of the recording electrode. The shape, size, and latency of the response obtained by stimulating the nerve at different sites are measured. The conduction velocity can then be determined by measuring the distance between stimulation sites and the time it takes to measure a response. This measurement can determine the fastest conducting fibers along the intervening segments of the nerve. The normal range of maximal motor conduction velocity is between 50 and 70 m/sec in the arms, and between 40 and 60 m/sec in the legs.

Sensory nerve conduction studies involve stimulating a sensory nerve and recording the response at another point along the course of the same nerve. Responses can also be recorded from a purely sensory nerve after stimulation of the parent nerve trunk from which it originates, or vice versa. This response is called the sensory nerve action potential.

# **Nerve Conduction Study Components**

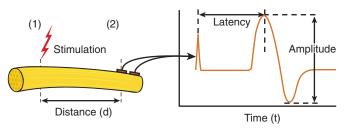

The parameters for interpretation of the EMG/NC-stat are (1) the standard sensory nerve conduction study, (2) the standard motor nerve conduction study, and (3) an F-wave study.

# Sensory Nerve Conduction Study

The components to evaluate this part of an EMG/NC-stat evaluation are as described earlier. The sensory response is termed the sensory nerve action potential (SNAP).

# Standard Motor Nerve Conduction Study

The components to evaluate this part of an EMG/NC-stat include recording, reference, and stimulating electrodes, as noted previously. This portion of the study creates a characteristic waveform. The calculation for motor velocity conduction occurs at proximal and distal sites along the nerve and is called the CMAP (Figs. 224-12 and 224-13).

**Figure 224-11** The testing sequence. Components of a sensory nerve conduction study are defined as follows: *Latency* is the time it takes the impulse to travel the distance (d) between the stimulator (1) and the detector (2), usually measured in milliseconds. *Conduction velocity* is the speed with which the impulse propagates, calculated as d/t, usually measured in meters per second. *Amplitude* is the height of the response, and can be measured from the baseline to the peak or from peak to peak for sensory responses.

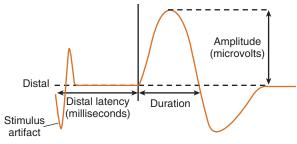

Figure 224-12 Compound motor action potential.

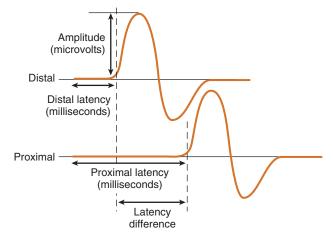

# Differentiating CMAP (Motor) and SNAP (Sensory) Responses

Several parameters differentiate CMAP and SNAP. The size of the signal involved is larger with CMAP. The signal is measured in millivolts rather than microvolts for SNAP. Although muscle can amplify the signal in CMAP, noise and other small artifacts can alter the quality of the reading with SNAP. CMAP can detect pathology in nerve and muscle, whereas SNAP can identify nerve changes only. The SNAP response is not affected by radiculopathies, whereas CMAP can be. The sensitivity of amplitude decrement to axonal loss is very high in SNAP because of the proportional relationship of amplitude to the number of axons in this study. This sensitivity is hard to overcome in CMAP because of vigorous muscle fiber reinnervation until advanced axonal loss occurs. As mentioned earlier, CMAP requires stimulation at two locations to evaluate conduction velocity, whereas SNAP requires only one stimulation site.

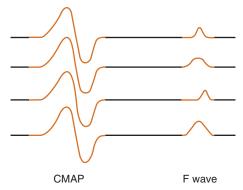

# The F Wave

The F wave provides information on the integrity of the entire nerve, from the root to the muscle. Because its measurement requires evaluating signals from every nerve traversing the entire spine, its latency is considerably longer than the CMAP's. The *minimum latency* is the most frequently reported parameter in most traditional studies. Its limitation lies in its having the lowest sensitivity because a single normal nerve fiber can read as a normal minimum latency. Measurement of these parameters is the function of the biosensor system of NC-stat (Fig. 224-14).

There are several F-wave response parameters that help to generate optimal sensitivity and specificity. These include *minimum F wave*, which is the earliest latency among the ensemble of recorded F waves; *chronodispersion*, which is the time between the earliest and latest responses in the ensemble; and *persistence*, which is the per-

**Figure 224-13** Comparison of proximal and distal compound motor action potential responses.

**Figure 224-14** Illustration of a compound motor action potential (CMAP) and F wave.

centage of stimuli that lead to a recordable F wave. Other factors that affect interpretation are the age, height, and temperature of the patient as well as appropriate stimulation and placement of electrodes or biosensors. The sum of all of these parameters, collectively, provide data to assist the clinician in coming to a meaningful clinical conclusion. By evaluating the nerve conduction data in their entirety, the clinician can assess how severe a nerve problem happens to be, the duration of the problem, and whether a nerve injury or muscle anomaly is generalized or involves specific nerves and muscles.

It is highly recommended that a clinician who wants to perform nerve conduction/EMG studies participate in a dedicated course in EMG waveform interpretation to understand the nuances of EMG interpretation. Suggested courses are found on the NeuroMetrix website. There is, however, a distinct advantage conferred with the NC-stat system in that the real-time automatic reports generated include very detailed waveform analysis and explanations that assist the clinician to correlate clinical findings with the most likely diagnosis without the patient experiencing the pain or discomfort of a needle prick. The report includes not only the waveforms and data but a preliminary diagnostic impression, which the clinician can confirm, refute, or include as additional commentary in the final diagnosis.

# **BILLING AND CODING**

# **CPT/Billing Codes**

95900 Nerve conduction, amplitude and latency/velocity study, each nerve; motor, without F-wave study

95903 Nerve conduction, amplitude and latency/velocity study, each nerve; motor, with F-wave study

95904 Nerve conduction, amplitude and latency/velocity study, each nerve; sensory

95999 Select Medicare carriers require the use of 95999, unlisted neurologic or neuromuscular code

# **Coding Multiple Nerves**

Units are used to indicate the number of nerves tested when coding nerve conduction studies. When performed with the NC-stat, a motor study with F wave of two separate nerves might be described as two units of 95903. Some payers have specific requirements for modifiers. For example, certain payers will require a specific local modifier to indicate billing for multiple nerves and, if not used, will reimburse for one nerve/unit of the procedure. Although nerve conduction CPT codes are designed to be billed per nerve by definition (no modifier needed), payers might not recognize this and reject this usage on a regular basis. A CMS 2000 OCI edit update suggested that the "-59" modifier be used with CPT code to indicate it is a

"distinct procedural service" being performed on a different area of the body (different nerve). It is good practice to regularly crossreference units billed with reimbursement received.

# **Coding Components**

Nerve conduction studies consist of a professional component, the amount paid for the physician's interpretation of the results of the study and associated overhead, and a technical component (TC), the amount paid for all other services (including technician and equipment costs). The global charge describes both the professional and technical components. Most payers will process and reimburse for the global (entire) procedure when nerve conduction studies are billed without modifiers indicating the separate components (TC or -26 modifier). Note that some payers have specific requirements for modifiers. For example, certain payers require a local modifier to indicate billing for the entire procedure and, if not used, will reimburse for one component of the procedure.

In essence, the real-time interpretation provided by NeuroMetrix is subject to the confirmation of the clinician providing direct service to the patient. Thus, the eligible charges are credited to the primary provider of the service. NeuroMetrix is able to sustain its support to the medical community by the sale of its biosensors. An example of characteristic payment for the procedure is given in Table 224-1.

# **Nerve Conduction Policy**

Medicare and other payers reimburse for medically appropriate nerve conduction studies. Most Medicare carriers have established lists of pertinent ICD-9 codes that indicate medical necessity for nerve conduction studies. Studies submitted with other diagnoses are considered not medically necessary and denied. Additional details for billing nerve conduction studies can be found in Medicare carrier Local Coverage Decisions (LCDs). The LCDs provide detailed conditions of coverage for nerve conduction procedures that address the following: type of procedures covered, number of nerves allowed, patients who are eligible to receive the procedure, requirements for providers of the procedure, the allowed testing frequency, and coding instruction.

# Frequency of Testing

Electrodiagnostic testing frequency guidelines have been established according to the American Association of Neuromuscular and Electrodiagnostic Medicine (AANEM). Repeat electrodiagnostic testing should not be necessary in a 12-month period in most cases. Tests refer here to any area tested with a group or region of nerve distribution, not the number of nerves. These guidelines have been incorporated into many Medicare and other payer policies. These limits should not apply if the patient requires evaluation by more than one electrodiagnostic consultant (i.e., a second opinion or an expert opinion at a tertiary care center) in a given year or if the patient requires evaluation for a second diagnosis in a given year. Additional tests may be required or appropriate over and above these guidelines. In such situations, the reason for the repeat test should be included in the body of the report or in the patient's chart. Comparison with the previous test results should be documented.

TABLE 224-1 Sample Reimbursement Rates for **Nerve Conduction Studies CPT Code** Global -26 Modifier **TC Modifier** \$32.38 \$57.98 95900 \$90.88 95903 \$96.63 \$46.48 \$50.14 95904 \$77.30 \$50.66 \$26.64

TC, technical component.

# Reimbursement

Medicare, workers' compensation carriers, and other payers reimburse medical providers for nerve conduction studies. Payment amounts and coverage policies for specific procedures vary by geographic location. To confirm reimbursement rates, consult with your local carrier or fiscal intermediary for specific procedure code reimbursement rates.

# Location

Nerve conduction studies are reimbursed in hospital and office settings. The Medicare Diagnostic Related Group (DRG) covers the technical component of Medicare services for inpatients. When submitting bills to Medicare, the physician may submit and be reimbursed for only the professional component of these studies. Although the physician cannot bill the carrier for the technical component under the DRG system, he or she may either bill the institution or establish a separate contract to receive the appropriate reimbursement. This rule also applies to non-Medicare payers using DRG payment methods.

# **Technical Specifications**

The NC-stat nerve conduction system meets or exceeds all the technical requirements for standard electrodiagnostic equipment. A detailed chart demonstrating each specification is available from NeuroMetrix on request.

# **Caveats**

 Because this technology is relatively new, a number of insurers consider this automated methodology "experimental" and will not pay for the procedures performed. New CPT codes that

- should specifically reflect this procedure with commensurate charges are scheduled to be released in 2010.
- The biosensors are expensive, but their accuracy is impressive. Always make sure that lead placement is accurate and contact points are clean. If there seems to be a malfunctioning unit, always recheck electrical contact points to ensure power is adequate.
- In the unlikely event reports are not timely, one can usually contact NeuroMetrix for support.
- Do your due diligence to evaluate the payment policy in your practice arena. One size does not fit all. Take advantage of some of the patient handouts supplied by NeuroMetrix. These remind the patient this is not a needle procedure.

# EMERGENCY DEPARTMENT, HOSPITALIST, AND OFFICE ULTRASONOGRAPHY (CLINICAL ULTRASONOGRAPHY)

Grant C. Fowler

For many reasons—including improvements in image quality, portability, and affordability, high-quality research about applications, and more widely available educational programs—real-time sonography has become a valuable tool for the primary care clinician. In many settings, patient care quality has been improved and lives have been saved because of immediately available information from realtime ultrasonographic scanning. Studies continue to demonstrate the safety and efficacy of sonography in the hands of nonradiologists, as well as to clarify its indications. As a result, the American College of Emergency Physicians (ACEP) has recognized the need for emergency ultrasonography imaging on a 24-hour basis and states that emergency physicians should perform such examinations. Such policy has been endorsed by the Society for Academic Emergency Medicine (SAEM), and since SAEM began encouraging residency programs to offer ultrasonography training, nearly all now provide it. ACEP considers focused, bedside ultrasonographic imaging to be within the scope of practicing emergency clinicians in the following areas: cardiac, pelvis, aorta, biliary, renal, trauma, venous thrombosis, and ultrasonography-guided procedures (an excellent reference is the ACEP Emergency Ultrasound Imaging Criteria Compendium, 2006). The American College of Surgeons now also offers courses and a CD-ROM on ultrasonography.

Although many of the applications in emergency medicine are useful for hospitalists and in the offices of primary care clinicians, ultrasonography in those settings has not been studied as extensively. However, when the principles of sonography are understood and the equipment is available, certain diagnostic and procedural applications can be learned during or after residency. Ultrasonography may improve not only the accuracy of making diagnoses and the performance of procedures, but how rapidly these are made and performed.

Because ultrasonography enhances physical examination skills, its use is also anticipated to enhance periodic health evaluations (PHEs). In so doing, cancer, carotid atherosclerosis, urinary retention, hydronephrosis, abdominal aortic aneurysms (AAAs), and other disease processes might be diagnosed earlier. One study (Siepel and colleagues, 2000) of ultrasonography-enhanced PHE in the elderly found a new diagnosis in 31% of patients who had already undergone a conventional physical examination. Seven percent of the patients required prompt treatment for a serious, unsuspected condition. Musculoskeletal ultrasonography has also evolved as an adjunct to the history and physical examination and to guide procedures for primary care clinicians providing musculoskeletal care,

especially those skilled in sports medicine (see Chapter 185, Musculoskeletal Ultrasonography). Both screening for atherosclerosis with ultrasonography and musculoskeletal ultrasonography have been endorsed by the American Institute for Ultrasound in Medicine (AIUM), and guidelines and videos have been developed. Ultrasonography has also been used by primary care clinicians to direct prostate biopsy (see Chapter 121, Prostate and Seminal Vesicle Ultrasonography and Biopsy).

Primary care clinicians already performing obstetric ultrasonography (see Chapter 172, Obstetric Ultrasonography) are often comfortable with the principles of sonography and capable of extending its use beyond obstetrics with little additional training. Primary care clinicians who use sonography when covering emergency departments or urgent care centers often extend its use into their hospital and office practices. Even primary care clinicians not comfortable using ultrasonography for diagnostic purposes may find it useful for procedures (e.g., insertion of central lines; guiding aspiration of bladder, breast or thyroid cysts, abscesses, or pericardial, pleural, peritoneal, or joint fluid), especially invasive procedures. Such use may help identify relative anatomy and pathology to minimize the number of attempts necessary when performing a procedure, thereby increasing patient safety. Having ultrasonography available may also increase clinician confidence when performing procedures. Gastroenterologists and nephrologists now use ultrasonography to direct liver and renal biopsies. The subspecialty of interventional radiology has grown very rapidly, and clinicians in this field frequently use ultrasonography to guide procedures formerly performed "blindly" by primary care clinicians. Surely, clinicians who have been performing these procedures "blindly" in the past should be able to enhance their skills with ultrasonography.

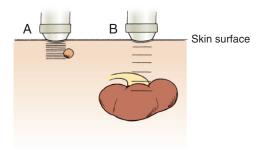

When first getting started, it is important to ask what clinical question(s) can be answered while scanning. Perhaps the answer in the emergency department can be provided with a *limited* scan rather than a *standard* or complete ultrasonographic survey. Sonographers and radiologists are trained for formal, complete ultrasonographic surveys. Applications for sonography in the emergency department are also defined as either *primary*, which have been evaluated and defined in the medical literature, or *extended*, which generally require more training or experience. Primary scans are often brief and goal oriented to answer specific questions raised by the clinical presentation. If a definitive clinical answer cannot be obtained with portable scanning, a formal study can then be ordered or consultation obtained.

Clinical ultrasonography is used as a component of the overall clinical evaluation of the patient. It is used in conjunction with historical, physical, and laboratory information and provides additional data for decision making and guiding procedures. It usually answers specific questions about a particular patient's condition or anatomy. Although other tests may provide more information in more detail, have greater anatomic specificity, or identify alternative diagnoses, clinical ultrasonography is noninvasive and rapidly deployed, and does not require the patient to visit another unit or facility. Furthermore, use of clinical ultrasonography avoids or minimizes the delays, costs, use of specialized technical personnel, and administration of contrast agents or exposure to biohazards (e.g., radiation). These advantages make clinical ultrasonography a valuable addition to available diagnostic and procedural resources. It is particular useful in time-sensitive or emergent situations.

# **PRINCIPLES OF ULTRASONOGRAPHY**

Similar to sonar used by submarines and fishing boats, ultrasonographic technology analyzes echoes from pulsed sound waves to generate images. Real-time sonography provides continuously updated or "live" images while the patient is being scanned. Live images often allow the clinician to immediately exclude certain diagnoses and to redirect clinical suspicions elsewhere. Live images may also improve the clinician's understanding of a particular patient's underlying anatomy. In addition, the best images are often obtained when scanning "live" because the clinician can immediately reposition the patient, if needed.

One general principle of ultrasonography is that the higher the frequency, the sharper the resolution of the image. However, the higher the frequency, the less depth of penetration there is into tissue (Fig. 225-1). With these principles in mind, the clinician chooses the probe, or transducer, that best matches his or her needs. Although recently developed probes can actually change between frequencies, most probes are dedicated to one frequency range—a high- (7.5 to 10 megahertz [MHz]), an intermediate- (5 to 7.5 MHz), or a low- (3.5 to 5 MHz) frequency probe. High-frequency probes are useful for scanning tissue close to the skin surface, such as breast or thyroid lumps, testicles, arteries, veins, or foreign bodies in the skin. Low-frequency probes are useful for scanning deep internal structures such as those of the abdomen, pelvis, and chest. (Even lower-frequency probes [2 to 2.25 MHz] are being used to scan obese patients.) Intermediate-frequency probes may be useful for scanning children. Linear probes are elongated and use parallel sound waves to produce a square or rectangular image (Fig. 225-2A). They require more surface contact, basically throughout the length of the probe, than sector probes. With sector probes, sound waves originate from one point source and are directed through a field to produce a pie-shaped image (Fig. 225-2B). Curvilinear probes are basically

**Figure 225-1 A,** High-frequency probe (7.5 to 10 MHz) provides higher-resolution images but cannot be used to scan deep organs. This probe is especially useful for organs or structures near the skin surface such as breast or thyroid tissue, veins, or arteries. **B,** Low-frequency probe (3.5 to 5 MHz) for deeper tissue such as abdominal or pelvic organs.

linear probes with a curved surface, also requiring less surface contact (Fig. 225-2C) and making it easier to scan areas where it is difficult to maintain good surface contact with a linear probe (e.g., between ribs).

Another principle of ultrasonography is that sound waves travel more readily and rapidly through solids and liquids than through air. Consequently, organs that are predominantly air filled (e.g., lungs, bowel), or any organs posterior to or surrounded by air-filled organs, may be difficult to image with sonography. In contrast, the liver, spleen, heart, bladder, and uterus (during pregnancy) are predominantly fluid filled and therefore provide their own excellent "windows" for imaging. They also provide windows to view surrounding organs or structures. A "window" is an area or organ near the body surface through which sound waves can easily be transmitted to obtain images. For tissue very close to the skin surface, such as thyroid, breast, and femoral veins, there is little tissue to be used for a window. In other words, there is little fluid between the probe and the organ. As a result, high-frequency probes often have their own built-in windows. Because ultrasound is best transmitted through solids and liquids, ample acoustic gel must also be applied between the body surface and any probe to form a good interface. Nevertheless, even with ample gel applied and excellent equipment, there will sometimes be difficulty obtaining images of certain organs for various reasons (e.g., inadequate window, organ obscured by bowel gas, body habitus, local trauma). In that situation, the reasons for being unable to scan an area or an organ should be documented and other imaging modalities considered.

NOTE: An after-market standoff or water path can usually be purchased and attached to a low-frequency probe so that, in addition to scanning deep organs, the same probe can be used for scanning near the body surface. If the clinician is not concerned about seeing bubbles, a bag of intravenous (IV) fluid can be used in the same manner, even if it is sometimes awkward to scan through it. Although a higher-frequency probe would certainly produce better images in this situation, for beginners, using a standoff with a low-frequency probe can save the cost of a high-frequency probe. This allows the primary care clinician to become very proficient with his or her "workhorse" or primary probe, usually a low-frequency 3.5-MHz probe.

Fluid such as amniotic fluid, urine, pus, or blood in the aorta or inferior vena cava appears dark by convention on an ultrasonographic image and is *sonolucent* (sound waves pass through it). Predominantly fluid-filled organs such as the liver, spleen, or renal cortex appear dark or gray on the screen with intermittent bright echoes within their structure. Solid objects such as polyps, bones, or gallstones are white or *echogenic* (i.e., produce a lot of echoes). If a solid object (calcified or hardened such as a gallstone) is larger than 3 mm, it should cast a well-defined shadow. This type of well-demarcated or "sharp" shadow can be differentiated from shadows cast by air, such as air in the gut. Artifact and shadows produced by air are often diffuse or "soft" and change considerably with changes in the placement, angle, or pressure of the probe or with peristalsis.

From a sonographic perspective, a cyst is any fluid-filled structure with smooth walls. Examples include cysts in the ovary, liver, or kidney, but also a full gallbladder, uterus during pregnancy, or full urinary bladder. In some ways, the inferior vena cava and abdominal aorta demonstrate cystic properties, such as the following:

- Cysts have smooth walls.
- No echoes or shadows are normally found in simple cysts.
- There is enhanced visualization of structures or tissue posterior to cysts.
- Cysts demonstrate a penumbra effect.

Because of the third property, cystic structures often serve as excellent windows for tissue being scanned behind or around them. The fourth property manifests as "semishadows," or what appear to

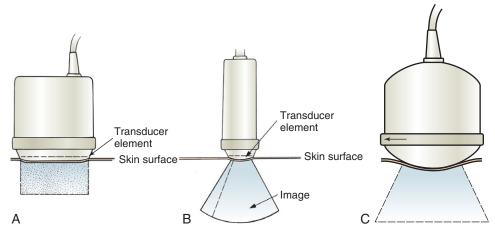

Figure 225-2 A, Linear probe produces a rectangular image and works especially well for obstetric scans. B, Wedge-shaped image produced by sector scanning probe may be adequate for most applications, depending on width of image. C, Curvilinear probe may be easier to maneuver between ribs. Note wedge-shaped image with curved anterior edge.

be shadows, often seen below both sides of a cyst and spreading outward (i.e., the penumbra effect). Combined, the appearance of all four acoustic properties may help confirm that whatever is being scanned is a cystic structure. These phenomena may be important after localizing a palpable mass, especially when trying to determine whether it is truly a cyst and might benefit from draining, or whether it is an adenoma.

# **OUALITY ASSURANCE**

For diagnostic purposes, to maximize accuracy and to minimize liability—especially for emergency scans—again, perhaps only limited, goal-directed scans should be performed. If the patient is possibly unstable, there may be time only for a limited study. Limited or focused studies can be used to answer a particular clinical question, to improve patient care, or as a follow-up to streamline patient care. Similar to interpreting plain radiographs, the clinician at the bedside knows exactly where the patient is experiencing pain. This information is helpful when interpreting limited scans, especially when there are abnormalities. In complex cases or in cases in which portable ultrasonography is inconclusive, if the patient is stable, referral for a formal study can be considered. If the clinical question cannot be answered with certainty, referral or consultation should be considered, especially if it might change the management. If these principles are followed, perhaps the rare yet most dreaded error of failure to diagnose can be avoided.

A quality assurance program should be implemented. This could consist of some method of tracking outcomes or comparing results. One method of comparing outcomes while the clinician is learning is to not charge for "beginner" or "learner" scans and to follow up every scan with a formal scan in the radiology department. Log sheets should be created and used to compare results with formal scans. Results should continue to be compared until an acceptable level of clinical accuracy is achieved. Although formal interpretations may differ slightly from "beginner" or "learner" interpretations, the evaluation standard is whether the formal interpretation will lead to a change in clinical management. Having a radiologist overread every scan is another method of ensuring quality; standard images could be obtained with each scan and then reviewed by a radiologist. Internet over-reading services by a radiologist are now continuously available (see the Suppliers section). With either method of quality assurance, proof of high-quality clinical data can be maintained and liability minimized, especially the liability of failure to diagnose. With these methods of quality assurance, the process of verifying and documenting clinician competence can be customized for each individual clinician.

For procedural purposes, there has been speculation that national hospital accrediting organizations will someday require many emergency department and hospital procedures to be ultrasonography guided. At the time of this publication, the author informally surveyed hospitalists and emergency medicine experts and found that none saw the need for such guidelines. Although there is individual variation, the literature suggests that the vast majority (>80%) of hospital and emergency medicine procedures are not currently ultrasonography guided. The majority of clinicians use ultrasonographic guidance only in those patients with a challenging body habitus or when there has been difficulty performing a procedure.

As with many procedures in primary care, beginners should develop a relationship with a consultant, either a radiologist or a clinician competent with ultrasonography (sonologist). Ultrasonography technicians (sonographers) often have extensive skill in multiple areas of ultrasonography and can be helpful consultants, especially in rural areas. As the clinician begins performing ultrasonography, cases should be discussed and consultation or supervision should be available.

# **CREDENTIALING**

For departments implementing ultrasonography as a procedure, in addition to quality assurance, policies should be in place regarding credentialing. Such policies should identify eligible providers, specify training or experience requirements, and specify the ultrasonography privileges. For certain clinicians, ultrasonography can seem quite simplistic, and it can even be seductive; operators may become overconfident. Without credentialing, the liability of failing to diagnose may increase with potentially catastrophic outcomes, especially in urgent care centers or emergency departments. The author knows of cases in which watchful waiting (e.g., leaking abdominal aortic aneurysm, ectopic pregnancy) was inappropriate management. These near-catastrophes could have been avoided with appropriate departmental policies, credentialing, or a supervision process.

Reasonable guidelines for credentialing nonradiologists in an emergency department require a minimum of 150 recorded scans for general emergency ultrasonography privileges or 25 scans per primary indication. For procedural ultrasonography, the clinician should demonstrate competence in the use of basic ultrasonography by being credentialed for at least one primary indication. ACEP (and the literature) supports these numbers and notes that the range needed to document proficiency is between 25 to 50 scans per primary indication. These scans should be followed up with formal scans, over-reading, or by tracking clinical outcomes to document

and demonstrate accuracy. At least 50% of the scans should show an abnormality. When competence for primary scans has been documented, scanning for other diagnoses (extended scans) can be managed on a case-by-case basis. Although there is much more to ultrasonography than can be learned by performing a certain number of scans, using these numbers as guidelines is helpful when attempting to decide whether a clinician is ready to demonstrate competence. There is also a process by which clinicians can be certified as registered diagnostic medical sonographers (RDMSs) after passing certain examinations and being supervised with scanning. It should be noted that the American Academy of Family Physicians does not endorse using a particular number of procedures performed (or documented) to credential for this or most other procedures.

# **LIABILITY**

When deciding whether using ultrasonography will raise a clinician's liability, the risk of not having ultrasonography immediately available should be weighed against making an incorrect diagnosis using ultrasound as a nonradiologist. For example, if certain diagnoses are not made urgently (e.g., pericardial tamponade, ectopic pregnancy, leaking aortic aneurysm, hemoperitoneum), patients may be endangered and liability may increase. In fact, failure to diagnose ectopic pregnancy is the second leading cause (in total dollar amounts) of malpractice awards against emergency physicians; ultrasonography is the initial procedure of choice to exclude ectopic pregnancy. For these and many other reasons, emergency clinicians now perform ultrasonography in most large emergency departments. Since ultrasonography training became routine for residents in emergency medicine, the standard of care also changed to that of a prudent emergency department physician, not a radiologist. Unfortunately, the standards of care for hospitalists and other primary care clinicians are not as well defined; therefore, documentation of competence, absolute certainty of interpretation, and overreading may be important.

# **DOCUMENTATION**

In many cases, ultrasonographic images are interpreted by the primary care clinician as they are being obtained. These interpretations often guide contemporaneous clinical decisions; however, a report needs to be placed on the patient's chart. It can be a handwritten, dictated, or templated note and should include the indication for the ultrasonography (e.g., preliminary diagnosis), what organs or structures were imaged, a copy of recorded images, appropriate measurements, and the final interpretation. If bowel gas or other technical factors prevent a thorough scan, these limitations should be identified and documented. Whenever feasible, images should be stored as part of the medical record and done so in accordance with facility policy requirements. Documentation is especially important if the clinician will be billing for ultrasonography; however, given the possible emergent use of ultrasonography by primary care clinicians, the timely delivery of care should not be delayed to archive images.

# **EQUIPMENT**

- Acoustic gel.
- For cardiac and abdominal scanning, a 2.5- to 5-MHz sector or curvilinear transducer and scanner is needed. These scanners, or a linear scanner of the same frequency, can also be used for transabdominal obstetric—gynecologic scanning.
- For transvaginal scanning, a 3.5-, 5-, or 7.5-MHz sector, linear, or curvilinear transducer can be used. Special transvaginal probes are manufactured at those frequencies. Again, the higher the frequency, the higher the resolution and the sharper the image. However, the depth of scanning is decreased with a high-frequency probe, so the transvaginal probe must be applied

# Box 225-1. Probe Frequencies and Potential Applications (from Low to High Frequency)

# 3.5 MHz

Abdominal Cardiac Lumbar puncture in morbidly obese Pelvic and obstetric Pleural effusion

directly to the cervix. For transvaginal scanning, a probe cover, plain-tipped condom, or examination glove is necessary to place over the probe.

- For pediatric or vascular scans, a 5- to 10-MHz sector, curvilinear, or linear scanner can be used.
- For scanning tissue close to the body surface (e.g., thyroid, testicular, breast)—also known as "small-parts scanning"—a high-frequency, 7.5- to 10-MHz sector, curvilinear, or linear scanner can be used (Box 225-1).

# **BEGINNER SCANNING**

Most clinicians learn human anatomy in three dimensions by dissection. Interpreting ultrasonographic images requires an ability to translate that knowledge into two dimensions. For proper probe placement and angulations, beginners should know that the best image is generated when the probe is perpendicular to the tissue being studied (Fig. 225-3). It may be helpful for beginners to minimize the planes of anatomy they have to learn by limiting their scanning to transverse and longitudinal planes. In other words, beginners should consider placing the transducer marker dot only toward the patient's right side (transverse) or head (longitudinal), while holding the probe perpendicular to the organ or tissue being scanned. If the probe can be held perpendicular to the skin surface, it is also usually easier to scan. Even for experienced sonographers, using these techniques may be helpful when getting oriented to a patient's anatomy at the beginning of any scan.

**Figure 225-3 A,** Best image is produced when the ultrasound beam is perpendicular to the organ interface. **B,** When the ultrasound beam is not perpendicular to the organ interface, scatter is seen, which may cause artifacts.

A

**Figure 225-4 A,** Marker dot toward the patient's right side produces a transverse image of the abdomen. **B,** Transverse image: kidneys (A), pancreas (B), liver (C), inferior vena cava (D), and aorta (E).

**Figure 225-5 A,** Marker dot toward the patient's head produces a longitudinal image of the abdomen. **B,** Longitudinal image: gallbladder (A), right kidney (B), perirenal fat (C), liver (D), and diaphragm (E).

By convention, when the marker dot is to the patient's right side, it produces a transverse image similar to computed tomography (CT) orientation (Fig. 225-4). The patient's right side will be to the left of the image on the screen. With the marker dot toward the patient's head, the image is what the clinician would see if the patient were dissected longitudinally and viewed looking into the body from the right side with the patient's head to the left of the screen (Fig. 225-5). A good impression of all of the anatomy and images of most organs can be obtained with longitudinal scanning, alone, at first.

**NOTE:** Some European manufacturers reverse the orientation so that the marker dot is found on the right side of the image.

# **INDICATIONS**

# Diagnostic Ultrasonography

# **Cardiac Indications**

 Electromechanical dissociation (EMD): narrow electrical complexes on electrocardiogram (ECG) without measurable blood pressure or clinical evidence of perfusion\*

- Evaluation of gross cardiac activity in setting of cardiopulmonary resuscitation\*
- Suspected pericardial effusion (enlarged cardiac silhouette on chest x-ray, electrical alternans or decreased voltage on ECG)\*
- Suspected pericardial tamponade (unexplained hypotension, prominent jugular venous distention, pulsus paradoxus, or EMD)\*
- Penetrating wounds to the chest (to exclude hemopericardium\*; see also the discussion of the focused assessment with sonography for trauma [FAST] examination, in the section on Trauma)
- Evaluation of global left ventricular function\*
- Gross estimation of intravascular volume status and cardiac preload
- Identification of acute right ventricular dysfunction or acute pulmonary hypertension in the setting of acute or unexplained chest pain, dyspnea, or hemodynamic instability
- Identification of proximal aortic dissection or thoracic aortic aneurysm

# Obstetric-Gynecologic Indications

- First-trimester vaginal bleeding\*
- Suspected ectopic pregnancy\*
- Threatened abortion\*
- Evaluation of fetal viability (e.g., maternal demise, maternal trauma, or inability to auscultate fetal heart tones by Doppler)\*
- Misplaced intrauterine device
- Suspected ovarian cyst, tubo-ovarian abscess, or adnexal/ovarian torsion
- Uterine fibroid

<sup>\*</sup>These indications have been evaluated and defined in the medical literature and are considered primary applications in emergency medicine. The remaining indications listed for scanning by nonradiologists have also been published, and in many cases studied extensively.

### **Abdominal Indications**

- Right upper quadrant (RUQ) pain\*
- Symptoms suggestive of biliary tract disease\*
- Suspected acute cholecystitis\*
- Obstructive uropathy and renal colic\*
- Hematuria
- Suspected renal abscess
- Pulsatile abdominal mass or suspected AAA\*

### Trauma

Suspected hemoperitoneum or hemopericardium (e.g., FAST examination),\* especially when real-time spiral (helical) CT is not available or the patient is not stable enough for CT (hemoperitoneum and hemopericardium need to be excluded in a patient with a history of blunt or penetrating trauma to the chest or abdomen or with an altered mental status and an acute abdomen)

### Miscellaneous Indications

- Rib fracture
- Pneumothorax
- Suspected proximal deep venous thrombosis\*
- Ultrasonographic evaluation of the bladder before suprapubic aspiration (SPA) or cannulation in infants or adults, or for documentation of postvoid residual (PVR)
- Subcutaneous foreign body
- Testicular pain or mass

# Combined Diagnostic-Procedural Ultrasonography

- Insertion of central lines\*
- Arterial puncture and cannulation
- Lumbar puncture or other spinal procedures in a morbidly obese individual (increasingly used by anesthesiologists, at least for localization of puncture site; see Chapter 206, Lumbar Puncture)
- Thyroid or breast mass or cyst, diagnosis or aspiration
- Pericardial effusion and ultrasonography-guided pericardiocentesis (see Chapter 214, Pericardiocentesis)
- Pleural effusion and ultrasonography-guided thoracentesis (see Chapter 95, Thoracentesis)
- Ascites and ultrasonography-guided paracentesis (see Chapter 201, Abdominal Paracentesis)
- Soft tissue abscess and ultrasonography-guided drainage (see Chapter 185, Musculoskeletal Ultrasonography)
- Joint effusion and arthrocentesis (see Chapter 185, Musculoskeletal Ultrasonography)
- Fracture, long bone, and fracture reduction (see Chapter 185, Musculoskeletal Ultrasonography)
- Endotracheal tube placement confirmation (see Chapter 213, Tracheal Intubation)
- Transvenous and transthoracic pacemaker placement (for localization of insertion site and when having difficulty with capture; see Chapter 216, Temporary Pacing)

# **CARDIAC ULTRASONOGRAPHY**

In the unstable hypotensive patient or the patient in shock, if there are narrow QRS complexes on the ECG, the diagnosis is EMD. The differential includes anything that could cause abrupt cessation of

\*These indications have been evaluated and defined in the medical literature and are considered primary applications in emergency medicine. The remaining indications listed for scanning by nonradiologists have also been published, and in many cases studied extensively.

venous return to the heart (including massive pulmonary embolism, tension pneumothorax, cardiac tamponade), acute malfunction of a prosthetic valve, and exsanguination. During resuscitative measures, exclusion of reversible causes is imperative, especially tamponade. Cardiac ultrasonography (echocardiography) is the diagnostic procedure of choice for excluding reversible causes of EMD.

A patient with a large pericardial effusion can be completely asymptomatic, deteriorate rapidly as a result of tamponade, or be in between. Several scenarios may lead the clinician to suspect a pericardial effusion (e.g., an enlarged cardiac silhouette on the chest radiograph, electrical alternans or decreased voltage on an ECG), especially in a patient at risk of an effusion. Pericardial tamponade may also result from a penetrating wound to the chest or be the cause of unexplained hypotension, prominent jugular venous distention, or a pulsus paradoxus on physical examination. Echocardiography is also the diagnostic procedure of choice for identifying and quantifying a pericardial effusion. Because rapid intervention is often a necessity in tamponade, ultrasonically directed aspiration of a hemodynamically significant effusion has become the treatment of choice.

Many emergency department clinicians, hospitalists, and cardiologists now also include a quick portable ultrasound of the heart when evaluating patients with chest pain. (See also Chapter 90, Echocardiography.) With this evaluation, gross cardiac activity can be assessed, including left ventricular function. Wall motion abnormalities (suggesting ischemia or scar) or severe valvular dysfunction may be noted, often early in the evaluation. Intravascular volume status can often be estimated, and right ventricular dysfunction or acute pulmonary hypertension identified (possibly indicating a pulmonary embolism). In the setting of chest pain, occasionally the diagnosis of proximal aortic dissection or a thoracic aortic aneurysm can be made.

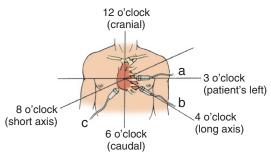

# **Preprocedure Patient Preparation**

Indications for the study and possible findings should be explained to the patient. The patient should be prepared to change positions, if possible, during scanning. He or she may experience some pressure from the probe as images are being obtained. Adequate gel should be applied to the parasternal, apical, and possibly subxiphoid areas of the chest wall. The patient should be in the supine or left lateral decubitus position when scanning is initiated.

# **Technique**

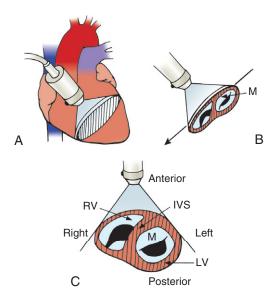

While viewing the front of the chest—if the 12 o'clock position is considered cephalic and the 6 o'clock direction caudal—note that the axis of the heart is directed toward the 4 o'clock position. Placing the marker dot of the transducer at about the 4 o'clock position produces the long-axis view of the heart, especially if the probe is located parasternally. The long-axis view is essentially the longitudinal view of the heart, if described in the conventional terminology of ultrasonography for the remainder of the body. Rotating the marker dot almost 90 degrees to the 8 o'clock position produces the short-axis view of the heart, which is actually a transverse view of the heart (Fig. 225-6). For unresponsive patients, those who cannot be moved, or patients with pulmonary hyperinflation (e.g., chronic obstructive pulmonary disease, intubated), a subxiphoid view may be useful. However, a subxiphoid view may not be possible in patients with abdominal distention or pain, so the clinician should be comfortable using several cardiac windows.

 With the patient in the supine position, place the low-frequency transducer in the parasternal (third to fourth or fifth intercostal space) or apical (inferolateral to the left nipple at the point of palpated maximal cardiac impulse) location. These are the same two traditional locations used for auscultation with a stethoscope.

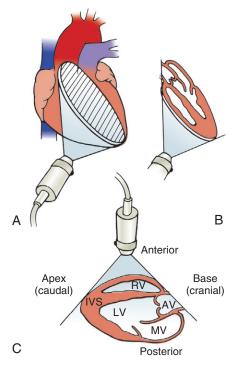

**Figure 225-6** Typical probe positions (placement) for emergency department echocardiography: a, parasternal position of probe; b, apical position of probe; and c, probe in subxiphoid position.

- 2. In the parasternal space, the probe or marker dot will be rotated to either the 4 o'clock (long axis) or 8 o'clock (short axis) position.
- 3. The short-axis view at the level of the mitral valve is often used to assess the adequacy of the window because the mitral valve is usually prominent and easy to locate. In this view, with the probe directed almost straight posteriorly, nearly perpendicular to the bed, the mitral valve produces the characteristic "fish-mouth" image (Fig. 225-7), especially if there is any degree of stenosis. This is basically a transverse view of the mitral valve. After this transverse view is obtained, if the probe is directed or angled superiorly, toward the patient's right scapula, the aortic valve can often be seen in cross-section. (This is more of an extended scan, so see also Chapter 90, Echocardiography, and Fig. 90-4.) Conversely, from the transverse view of the mitral valve, if the probe is directed or angled inferiorly, toward the patient's left hip, the papillary muscles of the mitral valve can be seen in cross-section (see Chapter 90, Echocardiography, Fig. 90-5). They are echogenic (bright white) structures, surrounded by fluid

**Figure 225-7** Short-axis view at mitral valve level. Probe is in parasternal position with marker dot at the 8 o'clock position. **A,** Ultrasonographic plane transects the short axis of the heart at the level of the mitral valve. **B,** Actual endocardiac structures viewed with probe in this position. M, mitral valve. **C,** Short-axis view as it appears on the ultrasonography screen. The image is displayed as if it is being viewed from the apex of the heart looking up toward the base. Note "fish mouth" appearance of mitral valve (M) as seen from this view. IVS, interventricular septum; LV, left ventricle; RV, right ventricle.

**Figure 225-8** Parasternal long-axis view of the heart. Probe is in parasternal position with the marker dot at the 4 o'clock position. **A,** Ultrasonographic plane transects heart through the long axis. **B,** Actual endocardiac structures viewed. **C,** Image as it appears on ultrasonography screen. AV, aortic valve; IVS, interventricular septum; LV, left ventricle; MV, mitral valve; RV, right ventricle.

in the heart (dark), which in turn is enclosed by the echogenic left ventricular walls seen in cross-section.

- 4. Directing the probe straight posteriorly, again perpendicular to the bed, the parasternal long-axis view can be obtained from the short-axis view by simply rotating the probe about 90 degrees counterclockwise (i.e., marker dot directed toward the 4 o'clock position; Fig. 225-8A and B). This is basically a longitudinal view of the mitral valve, with the echogenic ventricular septum located above the mitral valve on the image and the posterior wall located below it. The dark, fluid-filled right ventricle is located above the septum, and the left ventricle below it (Fig. 225-8C). To the right side of the image will be the aortic root, located to the right of the aortic valve and above the left atrium (see Fig. 225-8C). The left atrium in this view is located to the right of the mitral valve. The aortic valve cusps will also be seen opening and closing in a longitudinal view.
- 5. If the patient's position can be changed easily, place the patient on his or her left side. This allows the lingula of the lung to fall away from the heart and often provides a better window for all cardiac imaging.

**NOTE:** Some ultrasound equipment places the marker dot 180 degrees away from this standard orientation (i.e., the 6 o'clock position for some is the 12 o'clock position for others). To allow the user to determine the orientation of the probe, the marker on the image should be found. It corresponds with the marker dot on the probe.

6. In the apical location (again, a more extended scan, so see also Chapter 90, Echocardiography), the majority of scanning can be performed with the marker dot rotated toward the patient's right side or at the 8 o'clock position. The probe is then directed toward the patient's right shoulder. The apex of the heart will be in the center at the top of the image, with the septum also in

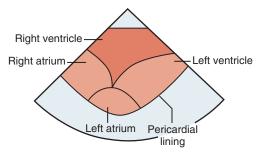

Figure 225-9 Subxiphoid (subcostal) view of heart.

the center and coursing vertically downward. The left ventricle and atrium will be on the right side of the image, and the right ventricle and atrium on the left, so it is called the *apical four-chamber view* (see Chapter 90, Echocardiography, Fig. 90-7).

- 7. A subxiphoid view may be needed to obtain a good window. Place the transducer directly below the xiphoid with the marker dot toward the patient's right side and angle it toward the patient's left scapula or even higher on the back. In fact, because the heart lies immediately beneath the sternum, the angle or plane of the probe will be almost horizontal or parallel to the patient's bed. A portion of liver will typically be seen at the top of the image (Fig. 225-9). Firm downward pressure may need to be applied with the probe, especially if the patient has a protuberant abdomen. Cardiac structures from this window will appear similar, but in a mirror image (rotated 180 degrees), to the parasternal long-axis view.
- 8. Search for fluid posterior to the heart. If present, it will usually appear at the bottom of the image. If found, quantify the amount of fluid (see Fig. 225-10). For various reasons (including body habitus) up to 10% of patients cannot be scanned adequately for a complete echocardiogram with portable equipment, even under optimal conditions. However, almost all patients with a clinically significant effusion can be diagnosed, so scan patiently and methodically. With a significant effusion, almost any view is acceptable. If an effusion is not readily apparent, vary the probe angles and amount of pressure applied on the probe for 5 to 10 minutes, if necessary, to find a window. Changing the patient's position may be helpful. All of these maneuvers may be necessary when there is a challenging body habitus or too much air in the lungs obscuring the image. If a good window is found with the parasternal short-axis view, many experts suggest using the parasternal long-axis view to exclude an effusion (see Fig. 225-8) because it provides a lengthwise image of the gravity-dependent portion of the heart (the posterior wall) when the patient is lying down. This is where a nonloculated effusion is most likely to settle.

**NOTE:** Even large effusions may develop gradually and not cause EMD or tamponade.

# Interpretation

### **Electromechanical Dissociation**

For patients undergoing cardiopulmonary resuscitation or with EMD, a subjective estimate of the organized cardiac activity can be made. Terminal cardiac dysfunction typically progresses from global ventricular hypokinesis with incomplete valve closure, to absence of ventricular wall and valve motion, to eventual cardiac standstill. This information, combined with the clinical scenario, may be helpful for determining futility during resuscitative efforts. Patients with poorly organized or absent cardiac activity on ultrasonography have a prognosis similar to that of patients with the ECG pattern of asystole (very poor). Patients with no obtainable blood pressure yet good cardiac contractility appear to carry a better prognosis, so an aggressive search for reversible causes of EMD should be pursued. If the EMD is due to pericardial tamponade, at least one chamber of the heart should collapse during diastole, and there will usually be a moderate to large pericardial effusion. However, even without identified collapse of a chamber, hemodynamic instability associated with a moderate to large pericardial effusion is suspect for tamponade. The cardiac activity is often well organized, with the rhythm regular and the rate tachycardic. Pericardiocentesis may be lifesaving. After the patient has been stabilized the findings should be recorded, including the size of the effusion.

# **Effusions**

A small amount of pericardial fluid may be physiologic. If an effusion is diagnosed, it should be quantified (small, moderate, large, or very large) and recorded (Fig. 225-10). Any hemodynamic compromise should also be noted.

- Small: With the patient in the supine position, pericardial fluid is confined posteriorly without anterior, lateral, or apical spread. It will be less than 10 mm width in diastole.
- Moderate: Effusion more evenly distributed anteriorly, laterally, and apically, no part greater than 10 mm width in diastole.
- Large: Effusion extends entirely around the heart, 10 to 20 mm width in diastole.
- Very large: Greater than 20 mm width as well as evidence of tamponade.

Epicardial fat pads can occasionally be mistaken for a pericardial effusion. However, epicardial fat pads usually have some internal echoes and are not distributed evenly around the heart. The descending aorta can also be mistaken for a pericardial effusion, but rotating the probe into a transverse plane will often help distinguish that structure. See Chapter 214, Pericardiocentesis, for treatment of a pericardial effusion.

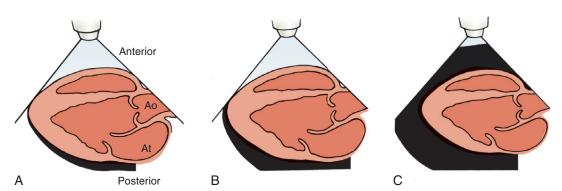

Figure 225-10 Effusions using a parasternal long-axis view. A, Small (may be physiologic). Ao, aortic root; At, left atrium. B, Moderate. C, Large.

# Global Left Ventricular Systolic Function

Published reports indicate clinicians can accurately estimate left ventricular ejection fraction (EF) as normal (EF >50%), moderately impaired (EF 30% to 50%), or severely impaired (EF <30%) with little training and experience.

# **Dilated Left Atrium or Aortic Root**

The diameter of the left atrium should be approximately the same as that of the aortic root on the parasternal long-axis view (see Fig. 225-10), and normal for both is about 2 cm. Disparities may suggest the need for a formal echocardiogram. A dilated aortic root may be suggestive of a thoracic aortic aneurysm, whereas an enlarged atrium increases the risk for atrial fibrillation and may indicate valvular or left ventricular dysfunction.

# Right Ventricular Function, Intravascular Volume, and Preload Assessment

Using the subxiphoid view (or during abdominal scanning), the inferior vena cava can be located. Comparing the maximal diameter of the inferior vena cava during exhalation with the minimal diameter during inhalation may provide a quantitative estimate of preload. Collapse of 50% to 99% is normal, complete collapse may indicate volume depletion, and less than 50% collapse may indicate volume overload, pericardial tamponade, or right ventricular strain or failure. However, it can also indicate acute right ventricular infarct, pulmonic stenosis, and chronic pulmonary hypertension. An estimate of preload can also be made by measuring the height of the meniscus sonographically in the internal jugular from the sternal notch and adding 5 cm.

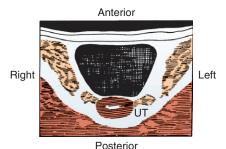

**NOTE:** Lack of right ventricular strain on ultrasonography does not exclude pulmonary embolism.

# Mitral Valve Function

The parasternal long-axis view (because it cuts the mitral valve lengthwise) can be used to assess the mitral valve quantitatively (M-mode) and qualitavely. The anterior leaflet is seen on the superior aspect of the image, and the posterior leaflet is located inferiorly (see Fig. 225-8). With real-time scanning, leaflets can be observed opening and closing. In systole, the leaflets should close to about a 90-degree angle from the septal and posterior walls and lie flat against the plane of the annulus. If the leaflets close and then billow beyond the 90-degree angle or the plane of the annulus, they are prolapsing, and a formal echocardiogram may be helpful to confirm the diagnosis. Severe prolapse can be the result of papillary muscle dysfunction or disruption due to an acute myocardial infarction. The apical four-chamber view (see Chapter 90, Echocardiography, Fig. 90-7) is also helpful for assessing mitral valve function.

# OBSTETRIC-GYNECOLOGIC ULTRASONOGRAPHY

With the advent of transvaginal probes, an alternative to transabdominal scanning became available for evaluating the female pelvis. Advantages of transvaginal over transabdominal scanning include the use of a higher-frequency probe with higher resolution, fewer tissue layers through which to scan (nine layers on transabdominal), resulting in less artifact, and less patient preparation required, especially regarding the bladder. These advantages allow an intrauterine pregnancy to be diagnosed by about 5 weeks after the first day of the patient's last menstrual period. Fetal cardiac activity can frequently be seen by 6 weeks. With transvaginal scanning, there is also a greater likelihood of visualizing an ectopic pregnancy in a tube or the adnexa. Disadvantages to transvaginal scanning include the necessities of an extra probe, a sheath, and additional training. Interpretation is slightly more confusing and the field of imaging is slightly narrower. Despite the fact that patients are becoming more

**Figure 225-11** Transverse view of the bladder. Note uterus (UT), viewed transversely, is found posterior to the bladder.

familiar with and accepting of this technology, transvaginal scanning is also slightly more invasive.

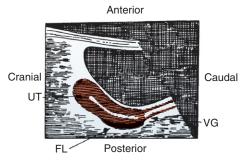

# **Transabdominal Scanning**

# **Preprocedure Patient Preparation**

The patient is scanned in the supine position. For an adequate window, the patient's bladder must be full, occasionally to the point of discomfort. For best scanning, the bladder should be so full that the dome extends 1 or 2 cm above the fundus. If scanning above the pubis does not immediately provide an adequate view, the patient's clinical stability should be evaluated. If she is stable, either a Foley catheter infusion of fluid (300 to 500 mL) or oral or IV hydration can be used to fill the bladder. If a Foley catheter is used to infuse fluid, the clinician should try to avoid instilling air bubbles into the bladder, which can cause echoes and produce a confusing image.

# Technique

- 1. Scanning the bladder first with a low-frequency probe and the marker dot at the patient's right side may help determine the shape and orientation of the uterus behind the bladder (Fig. 225-11). Because the bladder is rarely full of floating debris, the gain should be lowered until a minimal number of echoes are demonstrated in the bladder. This will decrease artifact. Confirm that the bladder, as opposed to a large ovarian cyst, is being used as a window. A large ovarian cyst is usually irregularly shaped, is oval or round, and often contains complex or echogenic contents. The bladder is basically square in a transverse view.
- 2. Turn the marker dot cephalad for a longitudinal view (Fig. 225-12). Often the uterus is not quite in the midline, as will have been demonstrated on the transverse view, so the probe may need to be rotated slightly out of the midline for a longitudinal image of the uterus. An echogenic line in the midline of the uterus is normal and represents the interface between the anterior and posterior endometria. A pair of dark fluid lines anterior and posterior to the central echogenic line represents endometrium during the proliferative phase. During the secretory phase, the

**Figure 225-12** Longitudinal view of the bladder. Note uterus (UT), viewed longitudinally, behind the bladder. Fluid in the cul de sac (FL) is found posterior to the uterus. VG, vagina.

endometrium becomes progressively thicker and echogenic. Scan the uterus from fundus to cervix. Occasionally an echogenic line known as the *vaginal stripe* may be visualized in the vagina, distal to the cervix. It represents another interface.

- Photograph and document any object or fluid accumulation within the uterus or posterior to it in the cul de sac (pouch of Douglas).
- 4. Scan the adnexa and note any fluid accumulations or abnormalities. Adnexa are usually located by first finding the midline of the uterus and then rotating the probe slightly. More specifically, with the probe producing a longitudinal view of the uterus, rotate it slightly clockwise (left adnexa) or counterclockwise (right adnexa) so that the marker dot is somewhat oblique to the uterus. If the adnexa cannot be located with this maneuver, move the probe laterally off of the midline and, while maintaining a longitudinal orientation, scan across and through the bladder to the opposite adnexa. In other words, angle the probe about 15 degrees off of the vertical to scan from the patient's left paramedian position. Scan across the midline through the bladder to visualize the patient's right adnexa, and vice versa for the left. The ovary often indents the wall of the bladder. Ovaries are oval structures of medium echogenicity and lie immediately anterior and medial to the internal iliac arteries, which are pulsatile and have echogenic walls. The iliac veins are also nearby. In women of reproductive age, demonstration of internal follicles often distinguishes ovaries from surrounding structures. Normal ovaries are 2.5 to 5 cm long, 1.5 to 3 cm wide, and 0.6 to 1.5 cm thick. Evidence of peristalsis on the patient's left side confirms that the colon is being scanned instead of the ovary.

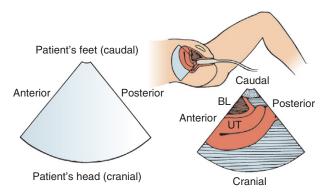

# **Transvaginal Scanning**

# **Preprocedure Patient Preparation**

The patient is scanned in the supine or lithotomy position. Transvaginal scanning is usually preceded by transabdominal scanning with a full bladder, perhaps allowing the clinician to make the diagnosis and, if not, to assess the overall anatomy. The bladder can then be emptied; however, some residual urine can serve as a useful marker for locating the bladder.

# Technique

- Prepare the probe by covering it with a probe sheath, a plainended latex condom, or an examination glove. Adequate gel should be placed on the tip of the transducer before covering it. Any bubbles between the cover and transducer should be smoothed out before scanning.
- 2. Perform a preliminary pelvic examination to relax the vagina as well as to evaluate for palpable masses. Determine the size, shape, and position of the uterus and define any areas of tenderness. Any tampons should be removed. Counsel the patient about the transvaginal ultrasonographic examination and obtain verbal consent.
- 3. While continuing to wear examination gloves, apply more gel to the transducer cover and gently insert the probe with posterior vaginal pressure to a position anterior to the cervix.
- 4. Scanning starts as soon as the transducer is inserted; avoid inserting the transducer too far, which can cause the clinician to miss the cervix and lower uterine segment. With the marker dot anterior, locate the midline of the uterus in the image.
- 5. Obtain both longitudinal and coronal scans of the uterus and adnexa by turning the marker dot anterior to the patient or toward her right side. For longitudinal scanning, the image orientation changes slightly (Fig. 225-13) compared with transabdominal scanning. Because the marker dot is pointed toward the anterior abdominal wall of the patient, the left side of the resultant image is actually anterior instead of cranial. Transverse orientation also changes slightly because true anteroposterior

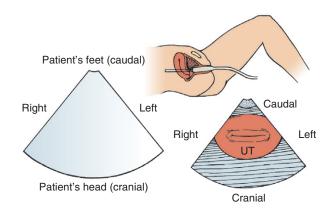

**Figure 225-13** Longitudinal orientation with transvaginal scanning. BL, bladder; UT, uterus.

- (AP) images of the uterus cannot be obtained by scanning from below. However, various coronal images are obtained that are similar to transverse images. The patient's right side remains on the left side of the image because the marker dot is turned to the patient's right side (Fig. 225-14).
- 6. Scan the uterus by performing a series of longitudinal, coronal, and oblique scans with the transducer at varying depths of penetration. Oblique views are obtained by rotating the probe with the marker dot in the longitudinal position to either the right or left side of the patient. Oblique views are used to scan the adnexa.
- Note any evidence of a fetus or fluid accumulations. Any areas
  of tenderness should be documented, along with any other
  important findings.

# First-Trimester Vaginal Bleeding

Approximately 25% of all pregnancies experience bleeding during the first half (see Chapter 172, Obstetric Ultrasonography, for differential). Abdominal pain is also common during pregnancy. Ultrasonography is recommended as the first test in patients experiencing bleeding or pain beyond 5 to 7 weeks after their last menstrual period. Two frequent causes of first-trimester vaginal bleeding are ectopic pregnancy and threatened abortion.

**NOTE:** If a fetal heart beat is demonstrated by the less expensive hand-held Doppler, pregnancy loss has effectively been ruled out and ectopic pregnancy is much less likely. Doppler heart beats are not heard until 9 or 10 weeks, and most ectopic pregnancies become symptomatic before that time. With a threatened abortion, demonstration of fetal heart beats decreases the likelihood of miscarriage to less than 10%. If the Doppler is used during a bimanual pelvic

**Figure 225-14** Transverse orientation with transvaginal scanning. UT, uterus.

examination and aimed directly at the uterine fundus as it is elevated by the examiner's hand, the likelihood of hearing fetal heart beats is much improved.

# Suspected Ectopic Pregnancy

Ectopic pregnancies vary in prevalence from 1 in 28 to 1 in 200 pregnancies. They account for the majority of first-trimester maternal deaths. The incidence has quadrupled since 1970, and there has been a sevenfold increase in maternal mortality. More than 40% of ectopic pregnancies are misdiagnosed on first presentation to the health care provider.

Clinical ultrasonography coupled with immediately available sensitive radioimmunoassay for human chorionic gonadotropin (hCG) has decreased the morbidity and mortality of ectopic pregnancies. It is important to correlate quantitative hCG levels in your laboratory with the type of equipment available to determine at what level of hCG an intrauterine pregnancy should be visible by sonography. This will vary depending on whether transabdominal or transvaginal scanning is performed.

# RISK FACTORS FOR ECTOPIC PREGNANCY (IN DESCENDING ORDER OF SIGNIFICANCE) AND SYMPTOMS

- Intrauterine device currently in place or recently used
- Previous tubal, abdominal, or pelvic surgery
- Prior ectopic pregnancy
- Prior sexually transmitted infection, especially pelvic inflammatory disease
- Infertility
- Recent therapeutic abortion

In several large studies, pain (97% to 100% of patients) and amenorrhea (74% to 84%) were more common complaints than vaginal bleeding, although bleeding occurred in the majority of ectopic pregnancies.

**INTERPRETATION: TRANSABDOMINAL SCANNING.** One technique for excluding or *ruling out* an ectopic pregnancy is to confirm or *rule in* an intrauterine pregnancy. With transabdominal scanning, to diagnose an ectopic pregnancy by actually visualizing the fetus in a tube or the adnexa is rare (<10% of ectopic pregnancies). Even with higher-resolution transvaginal scanning, only occasionally will the ectopic pregnancy be visualized (<25% of ectopic pregnancies).

To confirm an intrauterine pregnancy, a gestational sac with a fetus or fetal pole should be noted. A gestational sac appears as an anechoic (dark) structure within the uterus with highly echogenic borders. The first small echogenic structure seen in the gestational sac is the yolk sac at about 51/2 weeks. About a week later, a small collection of echoes may be seen; they constitute the fetal pole. The presence of a gestational sac with a fetal pole in the uterus reduces the chance of an ectopic pregnancy to about 1 in 30,000 cases. This figure represents the likelihood of a concomitant ectopic during an intrauterine pregnancy, the so-called combination pregnancy. Exceptions to this statistic are found in patients undergoing assisted reproduction in which the risk of combination pregnancy may be as high as 1 in 7000, or in patients taking ovulation-stimulating fertility drugs (e.g., clomiphene), in which the incidence may be as high as 1 in 100. If no fetal pole is seen within what appears to be a gestational sac, the clinician must consider that 10% to 20% of ectopic pregnancies produce pseudogestational sacs in the uterus and that the possibility of an ectopic pregnancy cannot be completely dismissed. The gold standard for diagnosing an intrauterine pregnancy is the visualization of embryonic cardiac activity. This may be seen as early as 7 weeks after the first day of the patient's last menstrual period or when the mean sac diameter is 12 to 16 mm, depending on the resolution of the equipment and the skill of the examiner. Mean sac diameter is determined by measuring a single diameter if the sac is round. It is the average of the three largest diameters (transverse, longitudinal, and AP) if the sac is oval. If a fetus is seen, gestational age can also be determined from what else

TABLE 225-1 Dates from Last Menstrual				
Period Correlated to Findings by				
Transabdominal Imaging				
Finding				

Finding	Weeks

Yolk sac	5–6
Fetal pole	6–7
Cardiac activity	7–8
Placenta	8–9
Somatic activity	9–10

<sup>\*</sup>Transvaginal imaging can usually locate the same finding I week earlier.

is visualized (Table 225-1). When a gestational sac with a mean diameter greater than 25 mm (17 mm for transvaginal scanning) lacks an embryo or when the gestational sac is grossly distorted, abnormal pregnancy is almost certain. Using these criteria, 76% of abnormal pregnancies and 93% of normal pregnancies will be correctly classified by only one ultrasonographic scan. The most accurate estimate of gestational age is at 9 to 11 weeks, using the crown–rump length.

If the patient is obese or her bladder is empty, transabdominal ultrasonographic findings may be limited; transvaginal scanning may be the only option. In all cases, failure to define an intrauterine pregnancy is interpreted in the proper clinical setting as an ectopic pregnancy until proven otherwise. Eight options exist when an intrauterine pregnancy is not demonstrated by ultrasonography (Table 225-2). Correlation with hCG titers may be necessary to complete the interpretation. With a healthy intrauterine pregnancy, hCG values rise predictably, doubling every 2 to 3 days for the first 8 weeks. In contrast, the hCG titer tends to rise at a slower rate in a patient with an ectopic pregnancy.

Evaluation of the medical literature for quantitative hCG titers correlated with sonographic findings often leads to confusion regarding the standards being used (for a crude conversion, the Second International Standard equals about 50% of the International Reference Preparation [IRP]). Most hospital laboratories are currently using the Second International Standard, whereas much of the early research used IRP. If the IRP standard of hCG quantities is used, transabdominal ultrasonography should detect an intrauterine pregnancy in 94% of cases when the quantitative hCG reaches 6000 to 6500 mIU/mL (3000 to 3250 mIU/mL for the Second Standard). This correlates with about 42 days' gestation.

Even if an ectopic pregnancy is not demonstrated by ultrasonography, there are associated sonographic findings (Table 225-3) that, if seen, significantly increase the likelihood of ectopic pregnancy. In the case of a ruptured ectopic, scanning the upper abdomen may reveal free fluid representing intra-abdominal hemorrhage. Although a moderate to large amount of fluid is highly correlated with an ectopic pregnancy, any free fluid is significant in the proper clinical situation. A demonstrated echogenic pelvic mass also significantly increases the likelihood of ectopic pregnancy.

If a normal intrauterine pregnancy is demonstrated, the search for other causes of the patient's symptoms might be facilitated with ultrasonography. The clinician should scan for evidence of urolithiasis, intact or ruptured ovarian or corpus luteum cyst, adnexal/ovarian torsion, tubo-ovarian abscess (dilated fallopian tubes/hydrosalpinx, usually bilateral, indicate pelvic inflammatory disease), or appendiceal abscess (appendicitis). Although a thorough description of the ultrasonographic findings for most of these situations is beyond the scope of this chapter, a ruptured ovarian cyst frequently is noted as an irregular adnexal mass, accompanied by fluid in the cul de sac, and evidence of clotting blood seen as an echogenic mass difficult to separate from the uterus. The appearance will be the same with a ruptured corpus luteum cyst; however, the ovary will be noted in the middle of the irregular adnexal mass. If color Doppler

<b>TABLE 225-2</b>	Possible Diagnoses If an Intrauterine Pregnancy Is Not Demonstrated by
Transabdom	inal Ultrasonography

Diagnosis	Finding	Management		
Confirmed ectopic pregnancy	Empty uterus and ectopic fetal heart activity	Surgery or emergent consultation		
Highly likely ectopic pregnancy	Empty uterus and echogenic pelvic mass or free pelvic fluid or hemoperitoneum	Surgery, culdocentesis or emergent consultation		
Very early normal pregnancy	Serum quantitative hCG <6000 mIU/mL IRP (3000– 3250 mIU/mL Second Standard)	Repeat quantitative hCG in 48–72 hr		
Occult unruptured ectopic pregnancy	Empty uterus or may see pseudogestational sac in uterus (seen in 10%–20% of ectopic pregnancies)	Surgery, consultation, or repeat quantitative hCG in 48–72 hr if stable		
Complete or incomplete spontaneous abortion	Empty uterus or atypical echogenic or sonolucent findings in uterus such as a misshapen sac, located low in the uterus, or debris in the sac	D&C to treat or confirm, consultation, or repeat quantitative hCG; emergency treatment necessary if cannot exclude ectopic pregnancy, if patient is unstable, or for heavy bleeding		
Dead embryo	Crown-rump length >5 mm and no cardiac motion after continuous observation	Serial quantitative hCGs or repeat ultrasonography in a few days; emergency treatment necessary only for heavy bleeding		
Embryonic resorption/blighted ovum	Mean sac diameter of >2.5 cm and no fetal pole or >2.0 cm and no yolk sac (see text for calculating mean sac diameter); also, a misshapen empty sac, located low in uterus, or debris in the sac	Emergency treatment necessary only for heavy bleeding		
Hydatidiform mole or trophoblastic disease	Snowstorm appearance of uterine contents	Consultation or D&C		

D&C, Dilation and curettage; hCG, human chorionic gonadotropin; IRP, International Reference Preparation.

is available, it may diagnose probable adnexal/ovarian torsion by demonstrating an enlarged ovary with absent blood flow compared with the opposite adnexa. However, two arterial sources supply the ovary, the ovarian and the uterine arteries, so normal blood flow does not exclude ovarian torsion. A torsioned cyst is often associated with a torsioned ovary, and may have a fluid–fluid level and a thickened rim of tissue, and be tender with palpation with the transvaginal probe. Urolithiasis is discussed in a separate section of this chapter.

**INTERPRETATION: TRANSVAGINAL SCANNING.** The interpretation for transvaginal scanning is the same as for transabdominal scanning, except that with a fetus everything is visualized approximately 1 week earlier than with transabdominal scanning. The correlations with hCG must also be corrected (see Table 225-1). Transvaginal scanning can usually detect an intrauterine gestational sac at 2000 mIU/mL IRP (1000 mIU/mL Second Standard) or about 35 days' gestation. For a patient with a quantitative hCG above this level and no intrauterine pregnancy visualized, ectopic pregnancy must be considered. If there is no vaginal bleeding, ectopic pregnancy becomes almost certain.

# Threatened Abortion

Management of a threatened abortion consists of ruling out possible causes (or treating them), assessing the amount of bleeding, and predicting the prognosis for the pregnancy. If bleeding is minimal and no specific cause is identified, such as infection (e.g., urinary tract or cervix) or anemia, the patient is discharged in most cases with instructions for bed rest, to minimize stress, and to increase hydration. If the evaluation can be completed entirely in the emergency department or the office, treatment goals are more readily

TABLE 225-3 Using Transabdominal Ultrasonography to Determine Risk of Ectopic Pregnancy in Patients with Positive Human Chorionic Gonadotropin and Empty Uterus

Ancillary Findings	Risk of Ectopic Pregnancy (%)
Any free fluid	20
Echogenic mass	71
Moderate to large amount of fluid	95
Echogenic mass with fluid	100
No ancillary findings	20

accomplished than if the patient must undergo a stressful evaluation in another department. Using specific sonographic criteria, the clinician may determine which patients need additional ultrasonographic studies as well as reasonably estimate the prognosis of the early pregnancy. Without ultrasonography, the only prediction the clinician can make is that 50% of threatened abortions will progress to miscarriage.

**INTERPRETATION.** Frequently, the diagnosis of threatened abortion is made after ruling out ectopic pregnancy. Presence of fetal cardiac activity is an encouraging finding in an early pregnancy because the risk of spontaneous abortion is less than 2% to 4% if fetal cardiac activity is seen after 12 weeks. The risk of miscarriage is less than 16% if cardiac activity is noted at less than 8 postmenstrual weeks, which is much lower than the 50% predicted if ultrasonography is not available or performed.

With earlier pregnancies (even before the embryo is visible), major and minor criteria are available for evaluating gestational sacs (see Chapter 172, Obstetric Ultrasonography). Again, patients with gestational sacs meeting most or all of these criteria by ultrasonography are much less likely to miscarry than the 50% rate predicted if the patients are evaluated by clinical means alone.

Failure to meet at least one major criterion is 100% specific in predicting spontaneous abortion. Fifty-three percent of abnormal pregnancies are identified by the same criteria. If there is a question about an abnormal sac, the patient should be scanned 7 to 10 days later. As an additional criterion during that time, the mean sac diameter in normal pregnancies should increase by about 1 mm per day.

Examples of abnormalities include low-lying gestational sacs (sacs in the cervical region) and abnormally shaped sacs. Both of these are worrisome findings and should be followed with a scan 1 week later. Frequently, low-lying sacs lead to spontaneous abortions, whereas abnormally shaped sacs lead to abnormal pregnancies. Worrisome findings also include failure of the sac to gain 1 cm in mean diameter in 1 week or the inability to visualize an embryo when the sac reaches 2.5 cm in mean sac diameter. These findings may assist the clinician in preparing the patient for the possibility of an abnormal pregnancy, such as one resulting in a spontaneous miscarriage.

Fibroids are present in 40% of women older than 40 years of age, have an echogenicity similar to the uterus (although the tissue is frequently organized in whorls), and can calcify. They are an overgrowth of uterine tissue and may be intracavitary, submucosal, intramural, subserosal, or pedunculated. Intracavitary fibroids almost always cause cramping and bleeding. Subserosal fibroids lie on the edge of the uterus and may indent the bladder, submucosal fibroids

border on the endometrial lining, and intramural fibroids lie entirely within the myometrium. Pedunculated fibroids are connected by a neck to the body of the uterus and may be confused with adnexal masses.

# **Evaluation of Fetal Viability**

Detection of fetal heart activity by the second and third trimester of pregnancy should be reliable by transabdominal scanning (see Chapter 172, Obstetric Ultrasonography). Earlier detection may require transvaginal scanning.

# Interpretation

Absence of fetal movement after scanning for a 5-minute interval in a pregnancy of more than 20 weeks' gestation is said to be 100% reliable for diagnosing a fetal demise. For a first-trimester pregnancy, if uncertainty exists about fetal heart activity, rescanning should be performed in 1 to 2 weeks.

Secondary criteria for fetal demise using ultrasonography include fetal anomalies such as hydrops, ascites, and pleural or pericardial effusions. Echogenic gas in the fetal heart and vessels may be early findings. Late findings include morphologic changes such as skeletal anomalies and unusual fetal positioning.

Reaction to external stimulation or uterine manipulation should cause brisk reflexes in viable fetuses as opposed to the passive motions seen with a fetal demise. Avoid misinterpreting the passive motions from uterine contractions around a dead fetus as fetal activity.

Because abruptio placentae cannot always be diagnosed with ultrasonography (i.e., it is a clinical diagnosis), ultrasonographic studies should be used in conjunction with maternal–fetal monitoring in the pregnant patient with significant abdominal trauma. A 4-hour monitoring period should be sufficient to identify fetal distress.

# Misplaced Intrauterine Device

Intrauterine contraceptive devices (IUDs) are approved for 5 to 10 years of continuous use. This length of time offers many opportunities to lose the string. When a string is not palpable on an IUD, possible causes include a properly positioned IUD in the uterus that has lost its string, an extruded IUD, or an IUD that has perforated the uterus and may even be lying in the abdomen. IUD users who have not lost the string also warrant further evaluation if they are experiencing cramping, pain, or abnormal bleeding. A flat-plate radiograph may document the presence of the IUD, but it will not help determine whether the IUD is in the uterus. Gynecologic instrumentation is another option, but instrumentation places the patient at risk of infection. In most cases, it should be reserved for removal of the IUD after the location is documented. Ultrasonography is usually the diagnostic procedure of choice to determine the location of an IUD. However, the diameter of most IUDs is less than 3 mm; therefore, scanning for IUDs in some cases is more difficult than expected.

# Interpretation

An IUD on ultrasonography produces a very straight, sharp-edged, echogenic image. Document the location of the IUD in both longitudinal (Fig. 225-15A) and transverse or coronal views (Fig. 225-15B). It may be accompanied by a small "ball" of echoes in the cervix—the string coiled up, which can often be retrieved with a cervical brush used for Papanicolaou (Pap) smears (see Chapter 146, Intrauterine Device Removal). If an IUD is not demonstrated and the posterior wall of the uterus is not easily identified, formal scanning may be necessary. IUDs may be difficult to locate when the uterus is retroverted.

Decidual reaction may mimic an IUD. To differentiate, an IUD should produce shadowing in at least one plane. Echoes from an IUD are typically straighter and sharper-edged than those from a decidual reaction.

**Figure 225-15** Intrauterine device in longitudinal (**A**) and transverse (**B**) views.

A perforation should be recorded as either complete or incomplete. For an incomplete perforation, a portion of the IUD can be demonstrated within the uterine wall. A flat-plate x-ray film may be necessary to document a complete perforation if it is not visible by ultrasonography.

# **ABDOMINAL ULTRASONOGRAPHY**

Various tests can be used when deciding whether conditions are good enough to perform a complete abdominal survey, especially if using portable equipment. The gain can also be set when performing these tests. First, if the bladder is full, an attempt should be made to scan it; if a full bladder cannot be scanned, the body habitus or conditions are probably not conducive for obtaining a complete abdominal survey. If the bladder can be scanned, the gain on the machine should be set low enough to eliminate echoes from a normally nonechogenic organ. Next, the clinician should attempt to scan the aorta lengthwise. Repositioning may be required, and the liver may be needed as a window. If the aorta is located, the gain should be set to minimize internal echoes because this organ normally has no echoes. (This gain setting can then generally be used to scan the majority of the abdomen.) If the clinician is unable to locate the aorta after several attempts and several minutes of scanning, body habitus or conditions may preclude a complete abdominal survey or scan. The clinician may be restricted to a focused or limited scan. The pelvis with a full bladder and the liver, right kidney, and RUQ structures will probably be easiest to scan. A referral may be necessary for a formal, complete scan for other abdominal structures.

# **Biliary Tract Disease**

Acute cholecystitis in the ambulatory setting in the United States results from obstruction of the cystic duct by gallstones in approximately 95% of cases. Unfortunately, the diagnosis of acute cholecystitis by purely clinical means (without ultrasonography) has an accuracy of only 50%, even with a positive Murphy's sign (pain over the gallbladder with palpation during inspiration). Therefore, realtime ultrasonography is the preferred diagnostic test for acute cholecystitis. A "sonographic Murphy's sign" combined with the presence of gallstones increases the diagnostic accuracy for acute cholecystitis to more than 90%. A sonographic Murphy's sign is described as pain elicited with probe compression over the gallbladder. Because early surgical management is now the treatment of choice for acute cholecystitis, early diagnosis is also important. Bedside ultrasonography is useful in diagnosing most cases of cholelithiasis and acute cholecystitis; however, obscure cases may require additional studies.

# **Preprocedure Patient Preparation**

If possible, the patient should have been in the fasting state for at least 8 hours; this ensures that the gallbladder is fully distended. Early-morning scanning may minimize bowel gas interference.

# **Technique**

1. Scan the patient in the supine position, longitudinally, with a low-frequency probe until you locate the gallbladder. It is usually located in about the mid-clavicular line, just above the inferior edge of the liver; however, it can be located anywhere between the midline and the anterior axillary line. A combination of subcostal and intercostal windows may be needed. Sustained inspiration by the patient may move the liver below the ribs and improve the subcostal window. The normal gallbladder is a cystic structure; when distended, it demonstrates the sonographic properties of cysts elsewhere in the body. The walls are smooth, usually no echogenic matter exists between them, and tissue behind the posterior wall is more clearly defined.

Other cystic structures located nearby that can be confused with the gallbladder include hepatic cysts, hepatic veins, the portal vein, renal cysts, the duodenum, the inferior vena cava, and the abdominal aorta. Hepatic cysts have very thin walls and are usually located much deeper in the hepatic parenchyma than the gallbladder. Hepatic veins usually run vertically within the liver when the patient is supine. They also have very thin walls that are compressible with probe pressure. Veins also collapse with inspiration and expand with a Valsalva maneuver. If followed posteriorly, the location just below the diaphragm where the hepatic veins empty into the inferior vena cava can usually be seen. Although the portal vein has echogenic sidewalls similar to the gallbladder, it can usually be viewed coursing horizontally through the liver. Often, tributaries to the portal vein, such as the splenic vein, can be traced from their origin to where they join to form the portal vein near the liver. Renal cysts can usually be demonstrated as very thin walled and contiguous with renal tissue (Fig. 225-16). They are located much further lateral and posterior than the gallbladder. Although the abdominal aorta has echogenic walls, it demonstrates pulsations and can be followed distally. Pulsations transmitted from the aorta may also be noted in the inferior vena cava. Having the patient take in a large

- breath should collapse the vena cava; a Valsalva maneuver should cause significant dilation. The duodenum can usually be distinguished from the gallbladder because peristalsis is observed. Having the patient drink water can also stimulate and demonstrate peristalsis in the duodenum. Air in the duodenum usually casts confusing, irregular shadows as opposed to the sharp shadows of gallstones.
- 2. Compared with other abdominal organs, the gallbladder usually has a rather superficial location on the inferior edge of the liver. After locating the gallbladder with the probe in the longitudinal position, obtain a long-axis view by rotating the probe out of the longitudinal plane of the body until the maximal length of the gallbladder is visualized and an image recorded. The maximal transverse diameter of the gallbladder should also be measured and recorded.
- 3. Obtain additional views of the gallbladder by moving the patient into one other position: the decubitus (right side up) position or the erect position. Repositioning the patient helps to avoid missing stones that may have rolled into a dependent position out of view.
- 4. Attempt to identify the source of any local tenderness and scan that area. The porta hepatis, which consists of the common bile duct, the hepatic artery, and the portal vein, can often be located by following the portal vein from the confluence of the splenic vein and the superior mesenteric vein. Conversely, the portal vessels in the liver can be followed horizontally until they coalesce as the portal vein at the hepatic hilum. The portal hepatis also can be located by tracking the hepatic artery from the celiac axis. Color Doppler can help distinguish the common bile duct from the hepatic artery.

### Interpretation

An echogenic structure within the gallbladder is a gallstone if it shows prominent posterior shadowing, has circumferential bile visible in at least one view, and has demonstrated mobility when the patient is placed in various positions (Fig. 225-17). When

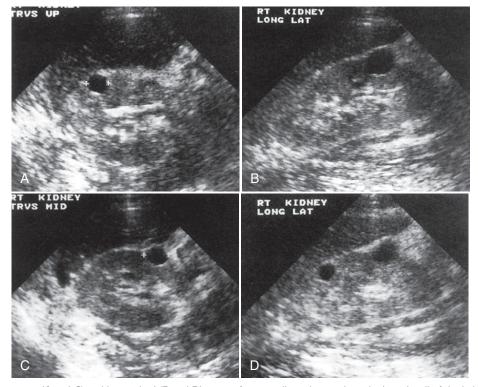

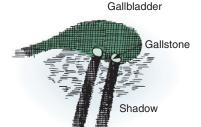

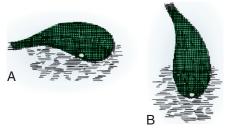

Figure 225-16 Transverse (A and C) and longitudinal (B and D) scans of two small renal cysts along the lateral wall of the kidney. Borders are smooth and well defined. No echoes are present. (From Hagen-Ansert SL [ed]: Textbook of Diagnostic Ultrasonography, 4th ed. St. Louis, Mosby, 1995.)

**Figure 225-17** Acoustic shadowing behind two gallstones. Note the "sharpness" of the shadow.

coupled with a positive sonographic Murphy's sign, this is diagnostic of acute cholecystitis. Otherwise, gallstones can have several variations when viewed sonographically:

- Nonshadowing: Gallstones less than 2 to 3 mm in size often do not cast a shadow. In that situation the differential also includes echogenic structures such as polyps or folds in the gallbladder. In fact, echogenic structures in the gallbladder that are nonshadowing are calculi in only 50% of cases. If, however, an echogenic structure is noted to have gravity-dependent motion, it is usually a stone (Fig. 225-18).
- Intermittent shadowing: Multiple small stones may form an irregular layer in the most dependent portion of the gallbladder. They may also cast a variable or intermittent shadow. This may be highly suspect for cholelithiasis, but further studies are necessary if there is no well-defined shadowing.
- Filled gallbladder: If the gallbladder is entirely filled with stones, bile may not be noted circumferentially around any one stone. Shadowing may be less prominent or hazy. Because a gas-filled duodenum can have the same appearance, it must be carefully eliminated from the differential by studying for other characteristics (e.g., peristalsis).
- Adherent stones: These can appear as echogenic structures that are not gravity dependent. If no shadowing is seen, further studies may be necessary to exclude a polyp, tumor, or fold, which can also be echogenic.
- Floating stones: Either one stone or a collection of stones may float and appear as an echogenic structure or a line of echoes in a nondependent portion of the gallbladder. If they do not cast a shadow, further studies may be necessary.
- Absent gallbladder: This sonographic finding (absence) may also be noted in a nonfasting patient or in one with chronic cholecystitis and severe scarring preventing expansion of the gallbladder. A patient with a completely stone-filled gallbladder, with a previous cholecystectomy, or with congenital absence of a gallbladder may also have a nonvisible gallbladder. If the gallbladder is not readily imaged and the patient is clinically stable, additional scanning should be performed several hours later with the patient fasting.

**Figure 225-18 A,** Gallstone is small and shadowing is not seen. **B,** However, it moves when the patient is repositioned.

Additional echogenic structures that can be noted in the gall-bladder include folds and septations (very common) or polyps (less common). These are immobile and do not cast shadows. Other possible findings within and around the gallbladder include the following:

- Increased diameter: A gallbladder diameter greater than 5 cm may be evidence of cholecystitis.
- Sludge: Low-level to mixed echogenic material that is slow to layer out after the patient changes positions may be gallbladder sludge. It most commonly represents biliary stasis and may occur in various conditions (e.g., obstructive jaundice, liver disease, sepsis) or in patients receiving hyperalimentation or certain other medications. It may also precede the formation of gallstones by a few years.
- Edema: A thin, dark line of fluid around the gallbladder wall may represent gallbladder edema, which can be found in acute cholecystitis or other conditions such as hypoalbuminemia, hepatitis, and ascites. In the situation where the patient has a sonographic Murphy's sign, discrete pockets of fluid may represent small abscesses. These abscesses are often near the fundus and are definitive evidence of acute cholecystitis.
- Thickening: Wall thickening is not specific for acute cholecystitis. The anterior wall is usually the easiest to measure. A rim of diffuse echogenicity greater than 3 mm thick may represent contraction after a recent meal, hepatic dysfunction, congestive heart failure, renal disease, ascites, sepsis, or neoplasms elsewhere (decreased osmotic pressure or elevated portal venous pressure). Patients with acquired immunodeficiency syndrome may also have diffuse thickening. Irregular wall thickening is also common with both acute and chronic cholecystitis. If no stone is present, yet the patient has a positive sonographic Murphy's sign, acalculous cholecystitis is a possibility.
- Dilated common bile duct: The normal common bile duct is less than 3 mm in diameter, but it can increase with age by 1 mm per decade without indicating a pathologic process.

Other entities, including hepatic tumors and abnormalities of the pancreas or portal system, would not usually be identified by a limited or focused examination. However, hepatic cysts are common (although not as common as renal cysts), are usually smooth walled, and demonstrate properties of cysts elsewhere. Hepatic malignancies usually demonstrate a variation in density from the normal surrounding tissue, but this can be very subtle.

# Obstructive Uropathy, Renal Colic, Hematuria, Renal Abscess

Obstruction of the collecting ducts of the kidney may be acute or chronic and unilateral or bilateral. Renal failure due to obstruction may be relatively asymptomatic, so an ultrasonographic study may be helpful, especially in those at risk (e.g., older man with benign prostatic hyperplasia). As much as 15% of American men will experience an episode of renal colic severe enough to require emergent medical attention. With flank pain and hematuria being the hallmark signs and symptoms for a stone, if a small stone is identified and the patient responds to analgesics, expectant management may be adequate. If available, real-time spiral CT scanning using a stone protocol has somewhat become the diagnostic procedure of choice for identifying stones. If a spiral CT is not available, studies have found that plain radiographs (KUB: kidney, ureter, and bladder) rarely change the clinician's management of renal colic. Intravenous pyelograms (IVPs) can be used when direct imaging of the urinary tract is necessary. Studies comparing sensitivity of ultrasonography and IVP have found them to be relatively comparable. However, most studies have found IVP to be somewhat more specific. Nonetheless, in certain situations, ultrasonography may be preferred over IVP (Box 225-2). Even if ultrasonography does not reveal the

# Box 225-2. Conditions in Which Ultrasonography May Be Preferable to Intravenous Pyelography

- Dehydration
- Contrast allergy
- Diabetes mellitus
- Differential diagnosis includes dissecting aortic aneurysm or acute cholecystitis
- Inadequate abdominal preparation for intravenous pyelography
- Poor venous access
- Pregnancy
- Renal failure or proteinuria
- Time constraints

diagnosis, at least it is noninvasive and certainly can be followed up with an IVP.

Evaluation of hematuria in the asymptomatic person probably warrants cystoscopy (see Chapter 111, Diagnostic Cystourethroscopy); however, it may warrant an ultrasonographic scan, even though evaluating all of the possible sources requires considerable ultrasonographic experience. The patient with a possible renal abscess (e.g., fever from pyelonephritis defervesced on IV antibiotics for a few days and then spiked again) may also benefit from ultrasonography, especially in the area of the original flank pain. Scanning the patient for possible renal trauma is discussed with the FAST examination.

**NOTE:** A leaking or dissecting AAA may produce signs and symptoms similar to left-sided renal colic, including hematuria. In fact, left-sided renal colic is the most common misdiagnosis in elderly

patients with a symptomatic AAA. In patients older than 55 years of age with left-sided renal colic, CT or ultrasonography should be considered to exclude this potentially fatal diagnosis that may be missed with an IVP.

# **Preprocedure Patient Preparation**

Under optimal conditions, the patient should have been in the fasting state for at least 8 hours to minimize bowel gas. Early-morning scanning may be preferable; bowel gas is usually minimal. Understanding that patients do not always come to the hospital or the office under these conditions, the clinician may need to hydrate the patient to increase hydronephrosis and enhance the acoustic window. Therefore, administering IV fluids may be not only therapeutic but helpful for making the diagnosis.

# Technique

- 1. Scan the patient in the supine position, longitudinally, with a low-frequency probe until the kidney is located. Kidneys are football shaped with a white stripe (echogenic renal sinus) down the middle. The renal sinus is surrounded by the echolucent renal cortex, which in turn is surrounded by the echogenic renal capsule (Fig. 225-19A). Compared with other abdominal organs, the kidneys are very posterior and lateral organs. On the right, the kidney is located at the posterior inferior edge of the liver, far lateral to the mid-clavicular line. Prolonged deep inspiration by the patient should bring the liver edge down from under the subcostal margin to improve the window and facilitate locating the kidney. Scanning between the ribs may also be necessary to obtain a good window through the liver.
- 2. The left kidney is located slightly higher than the right. On the left, the same maneuvers may enhance the use of the spleen as an acoustic window. Having the patient turn completely onto his or her right side to facilitate scanning in the coronal and transverse planes may also be helpful. Even scanning between

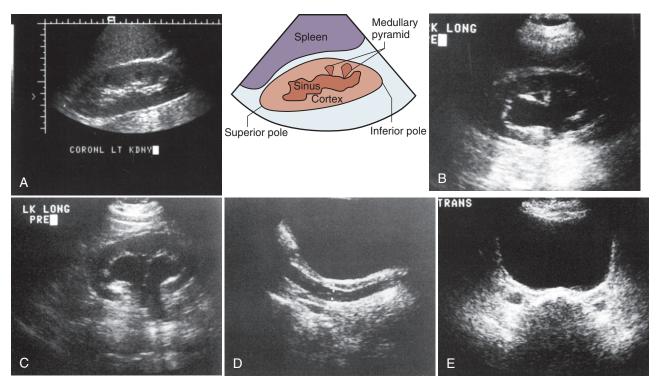

Figure 225-19 Longitudinal view of the left kidney (A), including inferior and superior poles. Pseudohydronephrosis of both kidneys (B and C) and ureters (D) associated with a full bladder (E). (A, From Simon BC, Snoey ER [eds]: Ultrasound in Emergency and Ambulatory Medicine. St. Louis, Mosby, 1997. B, From Hagen-Ansert SL [ed]: Textbook of Diagnostic Ultrasonography, 4th ed. St. Louis, Mosby, 1995.)

**Figure 225-20 A,** Mild hydronephrosis. Note hydroureters. **B,** Moderate hydronephrosis. **C,** Severe hydronephrosis.

the ribs from the back may be useful. Occasionally, having the patient sit in the erect position will bring the kidney into view. If no kidney is found on the left side, attempt to locate the kidney by scanning the pelvis for a pelvic kidney or the midline for a horseshoe kidney.

- After locating each kidney, with the probe in the longitudinal position, obtain a long-axis view. Rotate the probe out of the longitudinal plane of the body until the maximal length of the organ is visualized.
- 4. Attempt to assess for the presence or absence of hydronephrosis or hydroureter in both kidneys. Also attempt to locate any other intrarenal or extrarenal fluid collections, masses, or calcifications. The bladder should be scanned (see the section on Ultrasonographic Evaluation of the Bladder), especially if there is hydronephrosis or hydroureter.

### Interpretation

Because most episodes of renal colic are caused by small stones (2 to 4 mm), it is uncommon to actually visualize the stone. The confirmation of renal colic is usually made by demonstrating hydrone-phrosis or hydroureter in the correct clinical setting (flank pain, hematuria). Associated intrarenal calcifications further support the diagnosis. However, absence of hydronephrosis does not exclude the possibility of a stone; it may be small or have already passed.

The normal ureter is rarely visualized with the bedside ultrasonographic examination, so demonstration of a dark, fluid-filled ureter (hydroureter) is usually abnormal. With accumulation of additional fluid, as seen in hydronephrosis, the normal echogenic renal sinus stripe may actually be split by fluid, appearing as an intervening dark stripe. Along with this intervening stripe, the full appearance of hydronephrosis is characterized by increased fluid throughout the kidney, often contiguous with the hydroureter. Make sure the patient has voided before the sonographic examination because a very full or overdistended bladder can cause pseudohydronephrosis, which appears identical to mild or moderate hydronephrosis (Fig. 225-19B and C). Dehydration may also mask hydronephrosis, so IV hydration may be necessary before the scan.

When hydronephrosis is noted, an attempt should be made to follow the hydroureter(s) distally to the source of the obstruction. When associated with hydronephrosis, an echogenic structure found as the source of an obstruction, with or without prominent posterior shadowing, is diagnostic of urolithiasis. A stone larger than 3 mm should be highly echogenic and cast a well-defined shadow. With a good acoustic window and minimal bowel gas, the ureterovesical junction may be visualized and is a common place to find stones; stones commonly lodge at this level. Occasionally a stone will have passed this junction and be found in the bladder. Even if a stone cannot be located distally, scanning the kidney may reveal intrarenal calcifications. As mentioned previously, intrarenal calcifications associated with hydroureter support the diagnosis of renal colic due to a stone.

With moderate chronic hydronephrosis there is thinning of the renal medulla (Fig. 225-20A). With severe, long-standing, chronic hydronephrosis, there may also be thinning of the renal cortex (Fig. 225-20B and C). If bilateral obstructions are found, they are more likely due to an obstruction at the bladder outlet. In this situation, the bladder will be distended, should be easily scanned, and should be scanned carefully for the source of obstruction. One system grades hydronephrosis as mild or grade I (any hydronephrosis

up to grade II), moderate/grade II (renal sinus is split and confluent with calyces), or severe/grade III (causing effacement of renal parenchyma).

Hydronephrosis can be a normal finding in pregnancy, especially on the right side. Renal cysts may also mimic hydronephrosis. With ultrasonography, simple renal cysts appear like cysts elsewhere in the body. They have smooth borders and no echogenic material within them. Renal cysts are common, occurring in 50% of individuals older than 50 years of age. As opposed to hydronephrosis, renal cysts are well circumscribed and do not communicate with fluid outside the kidney (see Fig. 225-17). Renal cell carcinoma, which may appear as an echogenic mass in the kidney, can also cause hematuria. Transitional cell carcinoma can be seen as a mass anywhere along the length of a ureter or in the bladder. Fluid around the capsule, which appears as a dark stripe and can be irregular, may represent a perinephric abscess or, in the trauma patient, hemoperitoneum or a hematoma; hence, clinical correlation will be important.

# **Suspected Abdominal Aortic Aneurysm**

Unlike coronary artery disease and cerebrovascular disease, the incidence and associated mortality rate of AAAs continue to increase. Men are affected three to four times more frequently than women. The prevalence of AAA has climbed to 10% in people older than 65 years of age, and ruptured AAA has also become the 10th leading cause of death in men older than the age of 55 years.

The natural history of an AAA is to expand at a rate of 0.21 to 0.4 cm/year. Over 5 years, a 4-cm AAA has a 10% chance of rupture, a 5-cm aneurysm an 18% chance, and a 6-cm aneurysm a 30% or greater likelihood of rupturing. Controlling blood pressure and cessation of smoking may diminish the risk of rupture. At all comparable sizes, women may have a higher risk of rupture. Elective repair in most large centers has a mortality risk of less than 5%, compared with up to 80% in those patients who live long enough to reach the operating room after rupture. Therefore, elective resection is indicated for low- to moderate-risk patients with aneurysms that measure more than 5 cm in diameter.

# Risk Factors

- Male sex.
- 50 years of age or older.
- Use of tobacco.
- Hypertension.
- Family history of AAA.\*
- Other atherosclerotic risk factors may also be AAA risk factors.

The classic triad of ruptured AAA is pulsatile abdominal mass; low back, flank, or abdominal pain; and hypotension. Less than 50% of victims, however, possess this triad, and less than 25% are hypotensive on admission. Unfortunately, low back, flank, or abdominal pain is a frequent complaint for patients in the age group at risk for AAA. Patients with a leaking AAA may have many other signs and symptoms as well, including chest pain, ecchymoses, or a scrotal

<sup>\*</sup>Family history is most significant when a female relative has been diagnosed. Elastinolytic enzymes, decreased type III collagen, decreased elastin, and other biochemical variants are being studied to determine what is probably a multifactorially inherited etiology.

mass. The most common incorrect diagnosis in an elderly patient with a symptomatic AAA is left-sided renal colic. A leaking AAA may even be associated with hematuria; therefore any elderly patient with left-sided renal colic should be considered to have an AAA until proven otherwise.

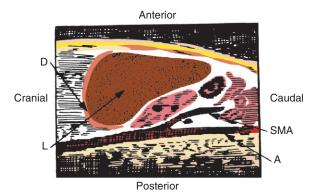

Most aortic aneurysms are found in the mid-abdomen, just above the iliac bifurcation (about the level of the umbilicus). Physical examination is extremely inaccurate for diagnosing AAA. Aortography may underestimate the size of an aneurysm if it is filled with thrombus or is dissecting, and lateral radiographs overestimate the possibility and size. Ultrasonography has been shown to be accurate in identifying both aneurysmal and normal aortas, especially infrarenally. For screening, ultrasonography is comparable with CT scanning, which is the gold standard for both diagnosis and estimation of size. However, ultrasonography may be a difficult study if there is a large amount of bowel gas, retained barium, or marked obesity. In addition, CT scanning is better than ultrasonography for identifying a leaking aneurysm, although ultrasonography may be useful when there is not enough time to perform a CT scan (emergent situation).

# **Preprocedure Patient Preparation**

Under optimal conditions, the patient should have fasted for at least 8 hours to minimize bowel gas. Early-morning scanning may also be preferable because bowel gas is usually minimal. Patients do not always present to the primary care clinician under these conditions; however, if a pulsatile mass is palpable through the anterior abdominal wall, it should be readily scannable. The patient should be informed of possible diagnoses and the indication for scanning.

# Technique

- 1. With a low-frequency probe and the patient in the supine position, attempt to define the general outline of the aorta with longitudinal scanning (Fig. 225-21). It is thick walled and pulsating. The inferior vena cava runs parallel and may be transmitting pulsations, but will be thin walled and will collapse with inspiration and distend with a Valsalva maneuver. If a pulsatile mass is palpated, it should not be difficult to determine whether it is contiguous with the abdominal aorta. If the aorta cannot be identified with longitudinal scanning, rotate the probe for a transverse scan and the aorta will often be revealed slightly anterior and to the left of the patient's vertebral body. A transverse view of the inferior vena cava will be noted to the patient's right (to the left of the image).
- 2. After defining the general outline, measurements should be taken of the largest AP diameter on transverse scanning at 1 to 2 cm increments from immediately below the diaphragm (at level of xiphoid) to a level 3 cm below the umbilicus. Measurements are taken from the outside wall to the opposite outside wall. Be aware

**Figure 225-21** Longitudinal scan slightly to the left of the midline showing normal structures and orientation. A, aorta; D, diaphragm; L, liver; SMA, superior mesenteric artery.

- that the transverse diameter of the aorta on a transverse scan may be exaggerated if the aorta is tangentially imaged when it makes a lateral turn. In addition, avoid applying too much probe pressure, which can also distort AP measurements. That being said, both AP and lateral transverse diameters should be measured because the lateral diameter of an AAA is often larger than the AP diameter. The lateral diameter may be slightly more difficult to obtain because the AP walls and diameter are usually more sharply demarcated.
- 3. If there is considerable truncal obesity or overlying bowel gas, increased surface pressure with the probe may enhance visualization. Immediately below the xiphoid, the liver can often be used as a window, especially if the patient suspends breathing briefly after a deep inspiration. Despite these maneuvers, bowel gas frequently obscures a 4- or 5-cm segment between the xiphoid and umbilicus. Using a rocking motion with the probe and scanning from above and below this segment may allow for a complete, systematic evaluation of the entire abdominal aorta. Turning the patient to the right or left lateral decubitus position may enhance scanning the aorta in the area of the kidneys, although the iliac bifurcation may not be visible unless the liver or spleen is enlarged. With the patient in the left lateral decubitus position (left side down), scanning intercostally from the right mid-axillary line may reveal the aorta lying "deep" to the inferior vena cava. Alternatively, placing the probe in the left paraumbilical region may allow evaluation of the distal aorta.

# Interpretation

With normal anatomy, mean abdominal aortic diameters are approximately equal in males and females during the second decade of life: 12.2 mm and 12.3 mm, respectively. By the eighth decade, the mean diameter increases to 22.8 mm in men and 16.9 mm in women. An AAA is defined by an aortic diameter of greater than 3 cm in a man and greater than 2.5 cm in a woman, or an enlargement of greater than 0.5 cm throughout the length of the aorta (the normal aorta tapers and decreases in diameter as it descends to its bifurcation). Surgery should be considered for any patient with symptoms compatible with an acute AAA and meeting these definitions because he or she is at risk for rupture.

If an AAA is found (Fig. 225-22) and the patient is hemodynamically stable, the clinician should attempt to determine whether branching vessels are involved and whether there is free intraperitoneal (in the manner of the FAST examination; see the section on Trauma) or retroperitoneal fluid (although ultrasonography is not always reliable for diagnosing retroperitoneal hemorrhage). Usually located along the left side of the spine or anterior to a kidney, the presence of fluid may indicate a ruptured or leaking aneurysm; surgical consultation should be obtained immediately. It should be noted that the lack of free intraperitoneal fluid does not rule out an acute AAA because the majority of acute AAAs present without free intraperitoneal fluid. If no fluid is visualized and the patient is hemodynamically stable, a CT scan may be useful to check for retroperitoneal hemorrhage. CT angiography and magnetic resonance angiography are best for delineating whether other arteries are involved. Again, surgery should be considered in any patient with persistent abdominal pain and a known AAA. At the same time, because AAAs are common in older patients, just because a patient has a new or known AAA does not guarantee it is the source of symptoms. Stents are now offered as an alternative (and probably safer choice) for patients with asymptomatic AAAs, especially those greater than 5 cm.

Most AAAs are fusiform and extend over a segment of the aorta; however, saccular aneurysms are often confined to a short segment. Therefore, to avoid overlooking an AAA, all segments of the aorta should be scanned methodically and systematically.

Echogenic material in the lumen may represent a thrombus or dissection. Alternatively, the clinician should check the gain setting elsewhere on the aorta to make sure it is not artifact. Large para-

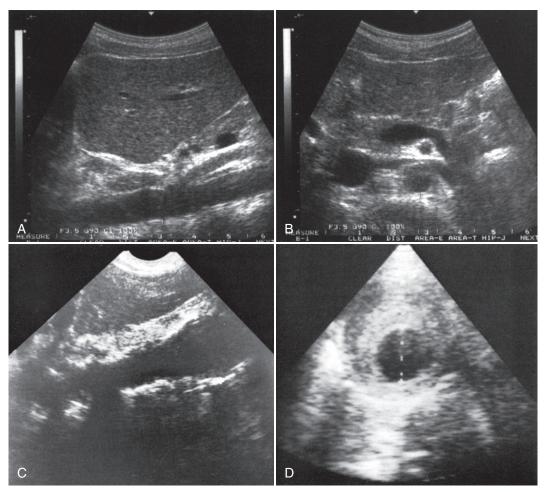

Figure 225-22 A, Longitudinal view of an abdominal aortic aneurysm (AAA). B, Transverse view of an AAA. C, Longitudinal view of intrarenal AAA. D, Transverse view of a rupturing AAA with thrombus. (A and B, From Simon BC, Snoey ER [eds]: Ultrasound in Emergency and Ambulatory Medicine. St. Louis, Mosby, 1997. C and D, From Heller M, Jehle D [eds]: Ultrasound in Emergency Medicine. Philadelphia, WB Saunders, 1995.)

aortic lymph nodes (usually anterior, but may be posterior and even displace the aorta away from the vertebrae) may be confused with the aorta or an AAA. However, compared with the aorta, nodes are usually irregular and nodular; color Doppler will demonstrate an absence of blood flow.

# **TRAUMA**

Studies indicate that physical examination fails to reveal significant injuries in 25% to 40% of trauma patients. Although a spiral CT scan may detect damage to abdominal organs, free fluid released from injured organs has long been used as a marker for significant injury. Over these years in the United States, diagnosis of intraperitoneal blood was made almost exclusively with diagnostic peritoneal lavage (DPL; see Chapter 204, Diagnostic Peritoneal Lavage). However, after dozens of prospective, controlled studies demonstrated the accuracy of ultrasonography for detection of hemoperitoneum, diagnostic techniques changed, first in Europe and Japan, and then in the United States. Investigators demonstrated that in the hands of capable, properly trained personnel, the sensitivity of ultrasonography for diagnosing hemoperitoneum was at least as great as that of DPL. In recent years, the FAST (focused assessment with sonography for trauma) examination was developed, which also includes a guick scan of the heart and pleural space. (See also the Miscellaneous section for a brief discussion of scanning for rib fractures or pneumothorax.) The indications for the FAST examination include but are not limited to traumatic injury to the torso. Not only

is such rapidly available diagnostic information very valuable in the emergency department, it may be very useful for triage in the setting of mass casualties or on the battlefield. There are no absolute contraindications to the FAST examination, and the only relative contraindications include morbid obesity, massive subcutaneous emphysema, and extensive abdominal or chest wall trauma because these patients may be difficult to scan. Patients with intra-abdominal fluid due to ascites, peritoneal dialysis, a ventriculoperitoneal shunt, a prior DPL, a ruptured ovarian cyst, or other pelvic inflammatory processes may also be difficult to evaluate. It may also be difficult to detect free fluid in some children and patients with isolated penetrating injury to the torso. The emergent need for laparotomy may be a relative contraindication; however, it may be important to make the diagnosis of pericardial tamponade or hematothorax with the FAST examination before taking such a patient to surgery.

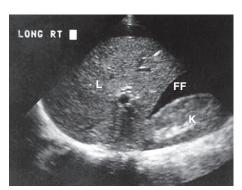

**NOTE:** Unfortunately, individuals who already have free fluid in the abdomen (e.g., ascites due to alcoholic cirrhosis) are often prone to abdominal trauma, and yet they frequently are not the best candidates for DPL or surgery. Serial ultrasonographic scans can be used in such patients to document rapidly increasing fluid; the decision can then be made whether this is likely due to bleeding and thereby justifies surgery.

# **Preprocedure Patient Preparation**

If the patient is hemodynamically compromised, attempts should be made to stabilize him or her before scanning. A full bladder may enhance scanning. The patient may experience some discomfort when scanning is performed over a contusion. The patient may also be asked to change positions.

# **Technique**

- 1. If the bladder is about to be emptied, consider proceeding to step 5. The location of initial scanning may also be determined by a history of or evidence of trauma over a particular area. Otherwise, most clinicians scan the RUQ first. This is the most important and easiest region to visualize and is usually the earliest and most accurate for detecting blood. Factors that may affect the sensitivity include the positioning of the patient and a history of prior abdominal surgery or intra-abdominal adhesions. If no fluid is seen in the supine position, Trendelenburg positioning may increase the sensitivity. Scan the patient's RUQ longitudinally with a low-frequency probe until you locate the right kidney. It is quite lateral and behind the organ used as a window, the liver. If the kidney is not immediately visible and the patient is conscious, have him or her inspire and briefly suspend breathing to bring the liver down. This often provides a better window and pushes bowel gas out of the way. If not, it may be necessary to scan between the ribs. The probe may need to be turned counterclockwise out of the longitudinal orientation to scan between the ribs. The probe may also need to be moved as far posterior as the posterior axillary line if bowel gas is interfering. The potential space located between the liver and the kidney is Morison's pouch (Fig. 225-23), also known as the hepatorenal space. This area, as well as the other spaces, should be scanned meticulously and in at least two perpendicular planes to rule out even a small collection of fluid.
- 2. If no fluid is seen in Morison's pouch, three additional potential spaces should be scanned in the RUQ. By angling the probe cephalad and using a gentle rocking motion, the pleural space above the echogenic diaphragm can usually be seen. The diaphragm will be moving with inspiration and expiration. Fluid above the diaphragm indicates either a hemothorax or a preexisting fluid collection (e.g., pleural effusion, empyema); fluid below it, in the subphrenic space, indicates intra-abdominal fluid. The potential space immediately below the kidney should also be scanned; it is actually an extension of Morison's pouch from above and the right paracolic gutter below.
- 3. Next, with the marker dot turned to the patient's right side, the probe should be moved to the midline and angled upward for a subxiphoid (subcostal) view of the heart and pericardium. The probe should be angled toward the patient's left scapula or even higher on the back, almost horizontal or parallel to the patient's bed. Again, the liver is usually used as a window. The area around the heart should be searched for fluid (usually located posteriorly,

**Figure 225-23** Fluid in Morison's pouch or hemoperitoneum. FF, free fluid; K, right kidney; L, liver. (From Simon BC, Snoey ER [eds]: Ultrasound in Emergency and Ambulatory Medicine. St. Louis, Mosby, 1997.)

- and possibly extending laterally) or evidence of tamponade. Avoid confusing a dark stripe due to pericardial fat pads, a pericardial cyst, or the descending thoracic aorta with a pericardial effusion. Scanning in more than one plane will usually help define the aorta. (See the section on Cardiac Ultrasonography for a discussion of subxiphoid scanning as well as alternative windows to use, such as the parasternal and apical windows, in case the subxiphoid view cannot be used owing to local trauma or body habitus.) Also, if pericardial fluid is noted, an attempt should be made to determine whether the patient has a diagnosis that could be associated with a preexisting effusion.
- 4. The probe should then be moved to the left upper quadrant (LUQ). Scan it longitudinally and survey the same four potential spaces that were scanned around the right kidney. The area should be scanned meticulously and the probe rotated to scan in at least two perpendicular planes to rule out small pockets of fluid. Scan the areas around the left kidney and spleen, the space between the kidney and spleen (splenorenal space), the pleural space above the diaphragm, the subphrenic space, and the space below the left kidney. The splenorenal ligament on the left side may prevent accumulation of fluid in the splenorenal space, so scanning the other areas around the spleen becomes more important. Similar to the right side, the space below the left kidney is an extension of the splenorenal space from above and the paracolic gutter below. Realizing that the spleen is smaller than the liver and often more difficult to locate, use modest inspiration to bring it down to facilitate a window. If subcostal scanning does not provide an adequate window, intercostal scanning may be necessary. Rotate the probe counterclockwise to fit between the ribs. Because it is even more likely that bowel gas will interfere when scanning the LUQ, the clinician needs to be very patient when scanning, rocking the probe gently. The probe may need to be moved even more laterally than on the patient's right side, beyond the posterior axillary line to the flank or the back.

NOTE: Scanning the paracolic gutters requires considerable sonographic experience. When scanning immediately beneath the kidneys, windows from above are usually available; however, when attempting to scan inferiorly, windows next to the iliac crests may be more difficult to locate. Large amounts of fluid surrounding the bowel may facilitate scanning; however, it usually requires more experience to be comfortable with declaring an absence of fluid. Although studies indicate that scanning this area only minimally improves the sensitivity, such scanning significantly increases the time required. Clinicians should also be aware that scanning these areas increases the number of false-positive findings because of confusion of soft tissue for fluid.

- 5. If the preceding scans are negative and the patient remains stable, the region of the pelvic cul de sac can be scanned after placing the patient in the reverse Trendelenburg or sitting position. Scan transversely by placing the probe immediately above the suprapubic bone, turning the marker dot toward the patient's right side, and angling the probe downward into the pelvis. Rock it gently and scan meticulously all planes of tissue from the dome of the bladder to the inferior aspect of the cul de sac. The marker dot can then be turned cephalad for a longitudinal scan, which sometimes allows a better appreciation of the pelvic anatomy. If time allows, a full bladder increases the sensitivity of scanning in this area; however, adequate views can often be obtained with a partly full bladder, especially if there are large amounts of blood. Conversely, if the bladder is empty, small amounts of blood in the cul de sac may be missed. In women, transvaginal scanning replaces the need for a full bladder and is exquisitely sensitive for free fluid (capable of visualizing as little as 5 mL).
- If the patient remains stable, serial scans may be helpful for detection of newly accumulating fluid. Conversely, if the patient suddenly becomes unstable, another scan may locate the cause.

# Interpretation

The entire examination can be performed very rapidly, with all four areas being scanned in less than 5 minutes. Intraperitoneal blood in small amounts usually first accumulates lateral to the right kidney. Fresh, unclotted blood has the same appearance as any free fluid in the abdomen. In the setting of a patient with a possible hemoperitoneum, the appearance of free fluid as a "dark stripe" is diagnostic (Fig. 225-24, and see Fig. 225-23) or a positive examination. As little as 10 mL has been diagnosed in the upper abdomen with transabdominal scanning; however, studies indicate the usual threshold for diagnosing hemoperitoneum is 500 mL. Therefore, a negative FAST examination does not preclude early or slowly bleeding injuries. A 1-cm fluid stripe roughly corresponds to 1 L of intraabdominal fluid. Again, Morison's pouch in the RUQ is one of the most sensitive areas to find fluid.

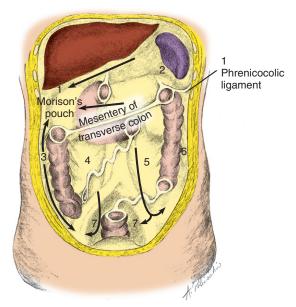

In the setting of trauma, the spleen is the most commonly injured abdominal organ. In the LUQ, fluid does not always accumulate between the spleen and the kidney; it can be located between the spleen and the abdominal wall. Conversely, it may completely surround the spleen (Fig. 225-24). Spontaneous rupture of the spleen occurs occasionally, such as in teenagers or individuals in their early twenties after an Epstein-Barr virus infection (mononucleosis). In that situation, fluid will usually be found surrounding the spleen.

Free fluid in the abdomen may also be due to urine or bile and denote injury to the urinary or biliary tract, respectively. With large amounts of blood, fluid may be visible from almost anywhere in the abdomen or pelvis. It may accumulate as fluid in the cul de sac (see Fig. 225-12). As soon as the clotting process begins, blood may produce variable echoes as the fibrin and degenerating cells become more prominent. As clotting progresses further, which can occur rapidly, the fluid may develop the sonographic qualities of soft tissue; however, such an accumulation of soft tissue is unusual in dependent areas such as the cul de sac.

Avoid confusing fluid in the stomach or bowels as free fluid; search for the peristalsis associated with this fluid. Likewise, avoid confusing a dark stripe due to perinephric fat with free fluid. Obese patients may have a significant amount of such hypoechoic perinephric fat. However, fat tends to accumulate along the upper and lateral aspect of the kidney, whereas fluid often completely surrounds the kidney. Comparison with the opposite kidney may demonstrate a similar accumulation of fat, confirming the false-positive result. Patients with multiple abdominal surgical scars and adhesions may accumulate fluid in different patterns and locations because the normal flow of fluid in the abdomen (Fig. 225-25) is disrupted.

**Figure 225-24** Free fluid in the left upper quadrant. (From Heller M, Jehle D [eds]: Ultrasound in Emergency Medicine. Philadelphia, WB Saunders, 1995.)

**Figure 225-25** Posterior peritoneum and reflections, indicating potential sites of intra-abdominal fluid localization and spread. I and 2, Right and left supramesocolic regions—above the transverse mesocolon and separated by the ridge of the lumbar spine; 3, right paracolic gutter; 4, right inframesocolic gutter; 5, left inframesocolic gutter; 6, left paracolic gutter; 7, pelvic cul de sac. *Arrows* indicate movement of free fluid (hemorrhage). (From Simon BC, Snoey ER [eds]: Ultrasound in Emergency and Ambulatory Medicine. St. Louis, Mosby, 1997.)

Likewise, adhesions in the chest may result in fluid accumulating in areas other than a dependent location.

After examining all four areas for free fluid, the liver, spleen, and kidney capsules and the parenchyma should be reexamined for disruption or hematoma. After a recent hepatic, renal, or splenic contusion, if an intracapsular hematoma accumulates it will usually appear cystic with irregular borders. A renal or splenic contusion with a ruptured capsule often appears as fluid surrounding either the kidney or spleen. Keep in mind it is more difficult to evaluate the spleen for such injuries because the spleen is normally hypoechoic in texture. Consequently, large intraparenchymal and subcapsular splenic injuries can be missed. To avoid missing clinically significant splenic injuries, the ultrasound, along with a hematocrit, should be repeated in 2 to 3 hours or if there is a change in vital signs. As it turns out, a negative FAST examination does not exclude most solid organ, mesenteric vascular, hollow viscus, or diaphragmatic injuries. Major disruptions of the capsules of all of these organs can be missed by ultrasonography; spiral CT scanning is more likely to diagnose such injuries.

# **MISCELLANEOUS**

There are many applications being used and further studied for ultrasonography in the emergency department, hospitalist, and office settings. For example, one published study found that rib fractures can be accurately diagnosed with ultrasonography. The entire outline of the affected ribs was scanned with high-frequency ultrasonography, searching for breaks in the normal smooth cortex. Accuracy, in certain situations, was better than that found with radiographs. Use of ultrasonography also spared the patient from radiation exposure. A pneumothorax may also be detected by scanning the rib interspaces anteriorly and longitudinally in the mid-clavicular line using a high-frequency probe. In the normal lung, pleural sliding should be noted in the somewhat superficial visceral-parietal pleural interface during respiration. Absence of normal pleural sliding suggests separation of the visceral and parietal pleura

due to pneumothorax. Although the following section is certainly not all-inclusive, it lists some of the indications in the emergency department, hospital, or office for which an ultrasonographic application has been either studied or published.

# **Suspected Deep Venous Thrombosis**

See Chapter 88, Noninvasive Venous and Arterial Studies of the Lower Extremities. Even when duplex equipment is available, compression ultrasonographic scanning using the high-frequency probe should be the initial study performed in most cases.

# Ultrasonographic Evaluation of the Bladder

Up to 8% of infants younger than 8 weeks of age in the emergency department with a temperature of 100.6° F or higher have a urinary tract infection (UTI). As much as 5% of infants younger than 2 years of age with unexplained fever have UTIs. The rate is 8% in girls and uncircumcised boys but less than 1% in circumcised boys. White girls have a much higher rate (up to 15%) than black girls. Boys are at the highest risk during the first 3 to 6 months of life.

Using an evidence-based approach, in those infants or children sufficiently ill to warrant immediate antibiotic therapy, the practice parameter of the American Academy of Pediatrics (AAP) recommends either SPA or transurethral catheterization to obtain a urine specimen. In those not sufficiently ill to require immediate antibiotics, the same diagnostic approach can be used; however, another option is available. If a urinalysis obtained by the most convenient means indicates a UTI, a sterile urine specimen should then be obtained in the same manner as listed earlier. These recommendations are based on a summary of the evidence and good clinical judgment; however, although a negative culture from a bagged specimen effectively rules out UTI, culture results are not available immediately. Bagged specimen cultures are also rarely negative, and unfortunately culture results cannot be predicted from urinalysis in most cases. Therefore, many clinicians opt for SPA or catheterization.

Although catheterization is less invasive than SPA, the process of catheterization may actually cause a UTI. SPA is inherently invasive, yet few serious complications have been reported, and numerous studies have demonstrated the superiority of SPA over alternative techniques. Limiting SPA to patients with proven full bladders further minimizes the risk to the infant (see Chapter 183, Pediatric Suprapubic Bladder Aspiration).

In adults, there are indications in the emergency department, hospital, and the office for SPA or suprapubic cannulation (SPC). SPA can be useful for obtaining a urine culture whenever a urethral catheter cannot be placed (or is contraindicated) or may be particularly useful in critically ill, potentially septic, or unresponsive adults. SPC is indicated whenever a urethral catheter is indicated yet cannot or should not be placed (e.g., trauma patients who have serious injury to the urethra, patients who recently underwent bladder or gynecologic surgery, or when a sufficiently wide catheter is unable to be passed through the urethra for diagnostic cystometry; see also Chapter 113, Suprapubic Catheter Insertion and/or Change, and Chapter 114, Suprapubic Tap or Aspiration).

Ultrasonography may also be used in adults to estimate PVR to evaluate the significance or status of urethral obstruction (e.g., significant prostatic hyperplasia) or a neurogenic bladder. PVR can be measured more precisely, albeit more invasively, by inserting a catheter; however, ultrasonography provides reasonable estimates of PVR in a much more comfortable manner with less risk of inducing an infection. Given the fact that recent studies have failed to document an exact level of PVR that would benefit from transurethral resection of the prostate (TURP) as opposed to watchful waiting, PVR estimates from ultrasonography may be more than adequate in that situation (considering TURP).

# Preprocedure Patient Preparation

The patient (or his or her parents or caregiver) should be informed about the indication for the study. If a suprapubic tap or cannulation is to be performed, counseling should be given for informed consent.

# Technique

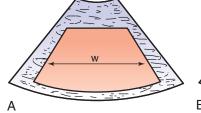

1. Infants should be placed in the supine, frog-leg position; adults should be supine. Perform the scanning in a transverse manner with a high-frequency transducer in infants. The marker dot should be directed toward the infant's right side, with the transducer placed slightly above the symphysis pubis. The transducer should be directed posteriorly or slightly caudad to locate the bladder. In adults, a low-frequency probe is used with the transducer and marker dot in the same location. The transducer should be angled in more of a caudal direction.

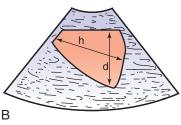

**NOTE:** In infants younger than 2 years of age, the bladder is an abdominal organ. As the pelvis grows, the bladder moves into the pelvis; therefore the transducer should be angled more caudad.

- Move and angle the probe to locate the maximal transverse diameter of the bladder. In infants, this is the probe location and angle to take measurements for determining whether the bladder is full. Take measurements in both the AP and transverse diameters.
- 3. For aspiration or cannulation, note the angulation of the probe necessary to locate the maximal transverse diameter of the bladder. Note the depth necessary to penetrate the bladder. The same angulation and depth should be used when directing the aspiration needle or trocar.
- 4. To estimate bladder volume in an adult, including PVR, three diameters should be determined. First, measure and record the greatest transverse measurement (*w* in Fig. 225-26A). Next, turn the marker dot cephalad and find the longest longitudinal plane. Measure and record the maximal superoinferior measurement (*h* in Fig. 225-26B) in this plane. In the same plane, with that same image, measure and record the maximal AP measurement (Fig. 225-27; see *d* in Fig. 225-26B).

# Interpretation and Results

In infants, a pocket of fluid larger than  $2 \times 2$  cm in the retropubic area measured in the AP and maximal transverse diameters defines a "full" bladder (see Fig. 225-27). In adults, the pocket should be much larger in order to reach it with a needle or trocar. Again, SPA

**Figure 225-26 A,** Greatest transverse diameter of bladder is shown by w. **B,** Maximal superoinferior measurement is shown by h; the maximal anteroposterior measurement is shown by d.

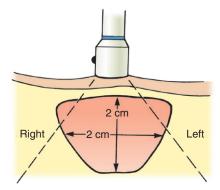

Figure 225-27 Transverse view of a full infant bladder.

or SPC should be attempted at the same angle with which the maximal transverse bladder diameter was measured (Fig. 225-28). One study resulted in obtaining urine in 79% of children meeting these criteria and undergoing aspiration. If the bladder is found to be empty and the patient is clinically stable, repeat scanning to search for a full bladder should be performed 30 minutes to 1 hour after the initial scan. If a full bladder cannot be found on the repeat scan, bladder catheterization should be considered.

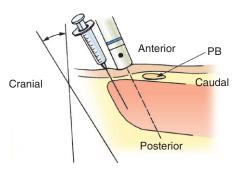

In adults, bladder volume can be calculated with this formula:

# $0.7 \times h \times d \times w$

This yields a standard error of approximately 21%. Although 21% may seem like a large error, as mentioned earlier, it is now known that no certain PVR threshold exists where surgery (TURP) ensures success and avoids future morbidity. For that reason, this crude measurement may be more than adequate. If more precise volumes are needed, more sophisticated formulas are available. In addition, software packages are available for more precise estimates using large machines that can take more precise measurements. Portable ultrasonographic equipment is also available that is used solely for making urologic measurements. Such equipment has been studied extensively and its accuracy has been documented.

# **Subcutaneous Foreign Bodies**

Missed foreign bodies are the second most frequent cause of lawsuits against emergency medicine clinicians. Objects composed of wood, plastic, glass, and vegetable material may not be radiopaque or visible with standard x-ray examinations. Modern military armor is also an example. Most is now fiberglass or cloth and therefore shrapnel is not often visible on routine radiographs. Although fine needles and splinters may be missed, high-frequency ultrasonography is usually helpful not only for confirming the presence of a foreign body but for localization before removal. (See also Chapter 18, Foreign

**Figure 225-28** Needle should be inserted next to the probe and parallel to whatever angle demonstrated the greatest diameter of the bladder. PB, pubic bone.

Body Removal from Skin and Soft Tissue, and Chapter 185, Musculoskeletal Ultrasonography.)

# Preprocedure Patient Preparation

The patient should be informed about the indication for the study and should understand that not all foreign bodies are visible with either ultrasonography or standard x-ray examinations. If a foreign body is located, the patient should decide whether he or she wants it removed. The patient needs an understanding of the possible complications of removing the object as opposed to not removing the object. (See Chapter 18, Foreign Body Removal from Skin and Soft Tissue.)

# **Technique**

- 1. In most cases, a high-frequency probe is preferred. For objects very near the skin surface, a standoff pad may be needed to raise the probe several millimeters off the skin. Such a device can either be purchased commercially or created using a latex glove filled with water or acoustic gel. Place the glove or pad on the skin and scan through it with the transducer.
- 2. Understanding that layers of normal subcutaneous tissue are not always uniform, scan in the area of the possible foreign body. Scan the contralateral "normal" side if unsure of the finding. Scan both longitudinally and transversely, and attempt to clarify the largest dimensions when located.

# Interpretation and Results

Foreign bodies may appear as hyperechoic in contrast to the surrounding tissue. If the resolution of the probe is great enough and the foreign body thick enough, an acoustic shadow may also be seen. Metal and glass are more echoic than plastic or wood. Foreign bodies may also be surrounded by a hypoechoic halo representing fluid or inflammation. The exact location of the foreign body should be marked; if it is not round, the predominant direction in which it is lying should be noted. The depth of the object, especially if it is to be removed, should also be noted.

# Testicular Mass or Possible Torsion

High-frequency ultrasonography is helpful in diagnosing testicular cancer as well as for differentiating the four most common causes for a scrotal mass: spermatocele, hydrocele, varicocele, and tumor. Transillumination with a bright penlight can often differentiate a spermatocele or hydrocele from other possible causes of a scrotal mass. When there is still a question after transillumination, ultrasonography is the procedure of choice.

Although radioisotope scans have been the procedure of choice for diagnosing a torsioned testicle, they often take hours to obtain, and time is of the essence when making this diagnosis. Because it can be performed fairly rapidly, color Doppler ultrasonography is becoming the diagnostic procedure of choice for testicular torsion.

# Preprocedure Patient Preparation

The patient should be informed about the indication for the study. Using a towel, the patient can retract the penis. The testicle and the scrotum are supported by the clinician's hand or by a towel under the scrotum. Either a very cooperative patient or an assistant may be needed to allow the clinician to use both hands for the ultrasonographic equipment.

# Technique

- 1. Using the same orientation as for the rest of the body, first turn the marker dot toward the patient's head for a longitudinal scan. Parallel longitudinal scans should be made with the high-frequency probe about every 5 mm.
- Next, turn the marker dot toward the patient's right side for a transverse scan. Transverse scans should also be made approximately every 5 mm.

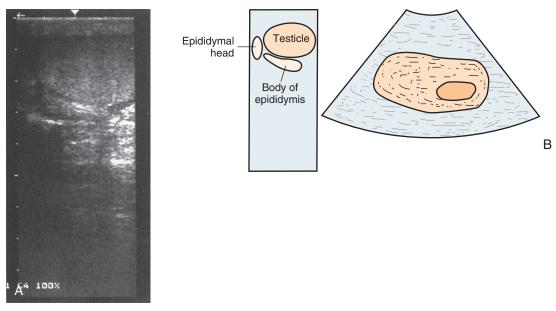

Figure 225-29 A, Normal testicular tissue with mediastinum testis. B, Testicular mass suspect for cancer. (A, From Simon BC, Snoey ER [eds]: Ultrasound in Emergency and Ambulatory Medicine. St. Louis, Mosby, 1997.)

The opposite testicle should be scanned, if indicated, or for a comparison for questionable areas. Any palpable abnormalities should be scanned.

# Interpretation and Results

Testicles are normally symmetric in size. A small amount of fluid in the scrotal sac is normal. A normal sonographic finding known as the *mediastinum testis* is seen as an echogenic longitudinal central line within the testicle (Fig. 225-29A). The epididymis usually appears as a slightly sonolucent structure posterior to the testes.

A small mass within the testicle is cancer until proven otherwise, especially in a patient younger than 40 years of age (Fig. 225-29B). A seminoma, the most common testicular tumor, usually appears as a hypoechoic mass within the testicle. Teratomas and embryonal cell cancers are usually irregularly echogenic.

Hydroceles, spermatoceles, and varicoceles should all be extratesticular. Spermatoceles are usually found superior to the

testicle and attached to the vas deferens. Hydroceles may surround the testicle and are predominantly fluid filled. Varicoceles are usually found in the region of the epididymis, extending superiorly. They will often increase considerably in size with a Valsalva maneuver.

A torsioned testicle often appears enlarged, less dense, and less echogenic compared with the normal testicle (Fig. 225-30A and B). The texture of the ischemic testicle is often blurry, and even sharp intratesticular markings (mediastinum testis) may be diminished. If available, color Doppler (especially spectral Doppler) usually reveals decreased blood flow on the torsioned side. However, flow cannot always be established by certainty with Doppler; if flow cannot be demonstrated in the opposite testicle, a radioisotope scan may be necessary to exclude torsion. If bilateral blood flow is documented and symmetric, the intratesticular markings are sharp and symmetric, and there is a difference in appearance between epididymides, epididymitis on the tender side is the likely diagnosis.

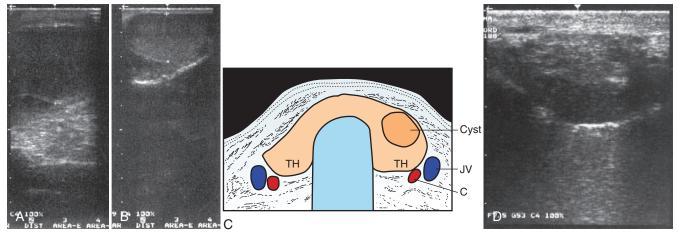

Figure 225-30 A, Torsion of right testicle demonstrated by an enlarged, hypoechoic testicle. B, Normal left testicle. C, Thyroid cyst. C, carotid artery; JV, internal jugular vein; TH, thyroid. D, Thyroid mass (adenoma). (A, B, and D, From Simon BC, Snoey ER [eds]: Ultrasound in Emergency and Ambulatory Medicine. St. Louis, Mosby, 1997.)

# COMBINED DIAGNOSTIC-PROCEDURAL ULTRASONOGRAPHY

Procedures can be guided either statically with ultrasonography or in real time. For the static technique, anatomic structures, the insertion site, and the angle and depth of insertion are first identified with ultrasonography, and then the probe is laid aside. If a fluid collection is to be aspirated, the amount can also be estimated (e.g., 1 cm³ equates to approximately 1 mL of fluid). The key portions of the procedure are then performed without ultrasonographic imaging. For the real-time technique, a sterile probe cover is used and the key components of the procedure are performed with simultaneous ultrasonographic imaging. A needle guide for the probe is helpful for real-time guidance; either a one-person or two-person technique can be used.

### Insertion of Central Lines

Several studies indicate that the use of ultrasonography as an adjunct for inserting central venous catheters not only decreases the failure rate, it decreases the overall incidence of complications as well as the number of attempts necessary. Consequently, the Institute of Medicine, the Agency for Healthcare Research and Quality, and the National Institute for Health and Clinical Excellence now recommend this technique. Patient satisfaction should also be improved. A real-time, two-person technique for internal jugular cannulation is described here. Similar techniques can be used for other sites (e.g., external jugular, subclavian, femoral). With the advent of tunneled catheters, such techniques can also be used to cannulate the brachial and cephalic veins for central venous access. Equipment is now available in many large intensive care units and other areas of the hospital that is portable and dedicated to the insertion of central lines. Such equipment may facilitate a one-person technique. It also frequently has a needle guide that attaches to or is built into the probe.

# **Preprocedure Patient Preparation**

See Chapter 211, Central Venous Catheter Insertion.

# Technique

- 1. For internal jugular cannulation, the patient is positioned supine, in 15 degrees of Trendelenburg, with the head turned slightly to the opposite side. (See Chapter 211, Central Venous Catheter Insertion, for techniques in locations other than the internal jugular.)
- 2. Perform a preliminary transverse scan with the high-frequency probe just above the clavicle near the insertion of the two heads of the sternocleidomastoid muscle. The pulsatile internal carotid artery should appear in cross-sectional view beside and medial to the larger internal jugular vein. With a Valsalva maneuver, the internal jugular will increase in diameter, significantly. Avoid applying too much pressure with the probe initially, which may temporarily collapse the vein and make it hard to locate. After it is identified, apply pressure to demonstrate that it is indeed collapsible as opposed to the noncollapsible carotid artery.
- 3. Cover the probe with a sterile cover (e.g., a sterile glove). A ribbon of acoustic gel should have been placed on the probe before covering; pay special attention to eliminating all bubbles between the cover and the head of the transducer. Prepare and drape the patient in the usual sterile fashion.
- 4. A small amount of sterile acoustic gel is placed over the site to be scanned. The sterilely gowned and gloved ultrasonography operator should be located next to the clinician (similarly gowned and gloved) performing the cannulation. The ultrasonographic probe should be operated beneath the drape to avoid interfering with the cannulation.
- 5. Position the probe so that the internal jugular vein is centered under the probe, which also means centered in the monitor screen. The person performing the cannulation should aim the

needle toward the center of the probe. Unless there is a needle guide, the needle will not always be visualized; if it is, it will appear as a linear, echogenic structure with shadowing. The needle will typically cause slight tenting of the vessel as it enters. The flash of blood in the syringe is often anticipated by the sonographer when he or she sees tenting of the vein immediately before the needle enters. After the flash of blood and confirmation of needle placement, if a guidewire is used it can often be visualized as it passes into the vein.

# **Arterial Puncture and Cannulation**

Techniques are described using a hand-held Doppler to assess collateral flow before arterial puncture and to facilitate arterial cannulation in Chapter 208, Arterial Puncture and Percutaneous Arterial Line Placement. The technique just described for ultrasonography-guided central venous catheter insertion can also be used to localize the vessel and then for arterial puncture and cannulation.

# Lumbar Puncture in the Morbidly Obese Individual

In morbidly obese individuals, lumber puncture is often complicated by the inability to palpate the spinous processes. The goal of ultrasonography is to locate the midline of the spine. (Ultrasonographic localization of the spine is also helpful for performing other spinal procedures and is being used more frequently by anesthesiologists.)

# **Preprocedure Patient Preparation**

See Chapter 206, Lumbar Puncture.

# **Technique**

- Ultrasonography can be performed either under nonsterile conditions, to mark the midline, or under sterile conditions for ultrasonographic guidance of the needle. A low-frequency probe is usually preferred.
- 2. With the patient in either the lateral recumbent or sitting position, apply adequate acoustic gel over the midline of the spine. Scan initially in transverse dimensions to locate a vertebra. The L4 spinous process should be noted below a line drawn between the iliac crests. When this vertebra is noted, maneuver the transducer so that the spinous process is centered on the monitor. Next, rotate the probe 90 degrees to scan longitudinally and locate several spinous processes. Mark the location and note the angle necessary to penetrate between the L3 and L4 spinous processes. After local anesthetic is given, insert the spinal needle and follow the remaining technique as described in Chapter 206, Lumbar Puncture.
- 3. To perform the scan under sterile conditions, cover the probe with a sterile barrier (sterile glove) as noted previously for central line insertion. When performing the lumbar puncture, use the same technique as for central line insertion and observe the needle passing over the L4 spinous process.

# Interpretation and Results

The spinous process should appear hyperechoic in contrast to surrounding tissue. The vertebral bodies should also be hyperechoic and cast shadows. Spinal fluid is rarely imaged between the spinous processes in adults, but the angles and depths to the vertebral bodes can usually be more clearly defined.

# **Thyroid Mass**

Palpable thyroid nodules occur in 3% to 4% of the population. One important goal when scanning a thyroid nodule is to determine whether there is more than one nodule. If multiple nodules are present (40% possibility), the risk of malignancy is very low (1% to

6%), with the exception of those who underwent low-dose irradiation. In the past, this was usually done for children with croup or acne; however, these treatments were stopped so many years ago that patients have likely outlived their risk (i.e., they would have already developed their malignancies). More recently, patients exposed to nuclear accidents such as Chernobyl or those exposed in the future to a terrorist "dirty bomb" may be at risk. These patients have a 30% to 40% lifetime risk of malignancy.

The next goal of scanning a thyroid nodule is to determine whether it is cystic (Fig. 225-30C), solid (Fig. 225-30D), or both (complex). Cold nodules on nuclear studies can be cystic with low risk of malignancy (20%), malignant (20%), or benign (60%).

If the nodule is cystic, aspiration may be an option and the fluid may be sent for cytologic analysis. Fine-needle aspiration is also an option for solid lesions.

# **Preprocedure Patient Preparation**

The patient should be informed about the indication for the study. If an aspiration is to be performed, the patient should be counseled for informed consent.

# **Technique**

- 1. With the patient in the supine position and the neck slightly hyperextended, apply an adequate amount of acoustic gel. Using a high frequency probe, scan transversely (marker dot to the patient's right side) in a lateral-to-medial fashion on one side. Next, scan the opposite side at the same level from lateral to medial. Apply minimal pressure at the midline to avoid obscuring the texture of the isthmus. Proceed in 5-mm increments throughout the entire gland.
- 2. Next, scan with longitudinal planes at 5-mm intervals. Observe each plane and then move medially from the carotid artery. Good surface contact is usually obtained at a 10- or 20-degree angle from the vertical. Scan the opposite side in the same manner.
- 3. For aspiration, see the next section, Breast Mass. If aspiration is to be attempted, mark the location. Note the angle and depth of any nearby structures that need to be avoided.

# Interpretation and Results

Carcinomas of the thyroid are usually single nodules with irregular borders, and most are hypoechoic. They can be cystic, solid, or both (complex), and they are frequently accompanied by adenopathy. However, there is no pathognomonic feature of cancer of the thyroid. If unsure, the clinician should consider fine-needle aspiration or surgical removal, especially for solitary nodules.

The most common thyroid masses are adenomas. Adenomas almost invariably occur as multiple lesions. They can appear with a halo of hypoechoic tissue surrounding a more echogenic mass, as a solid homogeneous mass with few internal echoes, or as a densely echogenic mass. Goiters appear as a diffuse, asymmetric expansion of the thyroid with a coarse texture. Multiple nodules are often present. Thyroiditis usually appears as a diffuse enlargement of the thyroid with multiple nodules. Parathyroid glands are rarely seen and usually appear on the posterior aspect of the thyroid near the carotid artery. They are relatively sonolucent; if larger than 5 mm, they are abnormal.

# **Breast Mass**

Ultrasonography is very helpful for evaluating breast masses, whether confirming the presence of a palpable mass or locating a nonpalpable mass seen on mammography, evaluating young fibroglandular breasts where mammography is less helpful, or differentiating solid from cystic lesions.

# **Preprocedure Patient Preparation**

The patient should be informed about the indication for the study. The patient should be aware that this procedure is being used only

to evaluate palpable lesions (or lesions noted on mammograms), to localize them, or to determine whether they are cystic or solid. It is not being used solely to exclude cancer. Portable ultrasonography may also be used to assist with aspiration of a breast cyst or with fine-needle aspiration of a suspected adenoma. Informed consent should be obtained if aspiration will be attempted.

# Technique

- Place the patient in the supine position. After application of acoustic gel, scan palpable lesions with a high-frequency probe.
   To locate nonpalpable lesions noted on a mammogram, scan longitudinally in 5-mm parallel increments in the appropriate quadrant. If the lesion is not located, scan in transverse increments through the same quadrant.
- 2. For cyst aspiration, either a one- or two-person technique can be used. The one-person technique may be adequate for large cysts, especially if they are readily palpable. The ultrasonography can be performed under nonsterile conditions. The goal of the ultrasonographic study is to locate the cyst, note the surrounding structures (especially those that should be avoided), determine the necessary depth for puncture, and mark the puncture site. The transducer can then be set aside and the procedure performed under sterile conditions as noted elsewhere (e.g., suprapubic aspiration, thoracentesis).
- 3. For smaller or deeper cysts that are difficult to localize, use the two-person technique. Just as with insertion of central lines, one person localizes the cyst with a high-frequency probe and keeps it in the center of the image while maintaining sterile conditions. The second clinician then punctures the cyst, also under aseptic conditions. Occasionally the needle can be visualized on the screen as it enters the cyst. The needle usually indents the cyst wall before it punctures.
- 4. After aspiration, the contents should be sent for cytology. A sample can also be prepared as a smear between two microscope slides that are then pulled apart, sprayed with the same fixative used for Pap smears, allowed to air dry, and sent for cytology.

# Interpretation and Results

Breast cysts have the sonographic appearance of cysts elsewhere in the body and are the most common breast masses in women between 35 and 50 years of age. They normally have smooth walls and an absence of internal echoes; therefore they are uniformly hypoechoic. Tissue behind the posterior wall of the cyst is usually more sharply defined than tissue anterior to the cyst. The penumbra effect may be seen.

The cyst should be measured in three dimensions: AP, longitudinal, and transverse. If aspiration is to be attempted, the depth necessary for penetration should be recorded. Nearby structures should also be noted.

Adenomas are usually ovoid, with lateral diameters larger than AP diameters. They usually have uniform and regular borders. If the gain is set improperly (too low) and no internal echoes are noted, adenomas may also appear cystic.

In contrast, ductal carcinomas usually have irregular borders and may be dense enough to cast acoustic shadows. Their AP diameter may be as great or greater than the lateral diameter. If they are blocking ducts, the ducts can often be traced to the site of the mass. Medullary carcinoma may be difficult to differentiate from adenomas, with the only differences being a more irregular border and more internal echoes. For this reason, solid solitary breast lesions should undergo either fine-needle aspiration or surgical removal.

Papillary carcinoma is fairly rare, but it can appear as finger-like projections protruding from a cyst wall. After cyst aspiration, if any tissue remains palpable, it should probably be surgically removed to exclude the possibility of papillary carcinoma. Also after aspiration, air can be reinjected into the cyst and a repeat mammogram performed. The location of the cyst will be marked by the air when the

mammogram is repeated. In this manner a mammogram can be used to help exclude papillary carcinoma.

# Pericardial Effusion and Ultrasonography-Guided Pericardiocentesis

See Chapter 214, Pericardiocentesis. Even when duplex equipment is available, plain ultrasonographic scanning using the low-frequency probe should be the initial study performed in most cases.

# Pleural Effusion and Ultrasonography-Guided Thoracentesis

Ultrasonography is an alternative to the use of decubitus x-ray films for confirmation of an effusion (e.g., patient with blunting of costovertebral angles on radiography). Once the effusion is confirmed, not only can the amount of fluid be quantified, but the best angle and the depth necessary for inserting the needle can be determined. In patients with a small amount of pleural fluid or a loculated effusion, routine thoracentesis is often unsuccessful and possibly dangerous. Ultrasonography-directed thoracentesis should minimize the danger while maximizing the results.

# Preprocedure Patient Preparation

The patient should be informed about the indications for the procedure as well as the risks and possible complications. The usual risks of pneumothorax, solid organ puncture, and procedural failure are reduced when thoracentesis is ultrasonography guided. Signed, informal consent should be obtained for thoracentesis. (See Chapter 95, Thoracentesis.)

# Technique

- 1. With the patient in the proper position (usually sitting and leaning forward, but can be supine or lateral decubitus), use a low-frequency probe to scan the back intercostally on the appropriate side, just above the liver or spleen. It may be helpful to actually scan the liver or spleen first, and to then move the probe in a cranial direction to locate the effusion. With the patient in the sitting position and the marker dot located cephalad, scan the entire thorax in longitudinal planes. After scanning near the midline, move the transducer laterally and map the dimensions of the effusion from superior to inferior, medial to lateral. Then turn the marker dot counterclockwise to fit between the ribs, and again scan to note the lateral dimensions of the effusion.
- 2. Mark the location of the largest collection of effusion that is safely accessible with the needle. The diaphragm will appear echogenic and moving with respiration; also note the location of the spleen or liver, and avoid inserting the needle in those locations. If the procedure will be performed with the patient in the supine or lateral decubitus position, be sure to demarcate the extent of the effusion relative to the hemithorax that will be accessible.

- Effusions may move with respiration, so note where to direct the needle relative to each phase of respiration. Plan to perform the insertion during the optimal phase. Note the depth necessary to reach fluid, especially for large or obese patients; an extra-long needle may be necessary for these patients. A needle stop, set to the appropriate depth, may be helpful for preventing penetration of lung tissue and causing a pneumothorax.
- 3. For smaller or loculated effusions, the thoracentesis is best performed with ultrasonographic guidance. Cover the probe with a sterile barrier (e.g., sterile glove) as noted previously for central line insertion. This procedure may also require two persons: one to hold the transducer while the other performs the aspiration. When performing ultrasonography-guided thoracentesis, use the same technique as for central line insertion. With the probe held scanning longitudinally, the top of the rib over which the thoracentesis is to be performed should be highlighted by the transducer. If a curvilinear or sector scanner is being used, the transducer should be held at the same optimal angle as that needed to reach the effusion. The thoracentesis needle should then be advanced to the appropriate depth at the same angle as the transducer. Again, a properly set needle stop may prevent penetrating lung tissue and causing a pneumothorax. Occasionally the echogenic needle will be observed passing over the rib. Once fluid is obtained, complete the procedure in the same manner as if it were not ultrasonography guided.

# Interpretation and Results

Pleural effusions that are predominantly fluid appear dark or hypoechoic on ultrasonography. They are located above the echogenic diaphragm, which moves with respiration (Fig. 225-31). An empyema may demonstrate echogenic objects in the fluid. Loculations and the diaphragm appear as echogenic borders to the fluid. Fluid located below the diaphragm (and not within an organ) is ascites.

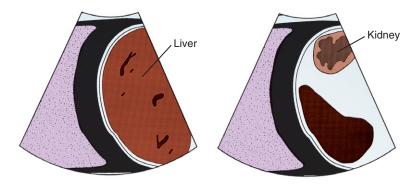

# Ascites and Ultrasonography-Guided Paracentesis

As discussed in the Trauma section, the presence of abdominal fluid is not always obvious on physical examination. Ultrasonography can be used to confirm the presence of ascites and to determine the best location for diagnostic paracentesis. Although routine paracentesis may be contraindicated in certain situations (e.g., in patients with adhesions from prior abdominal surgery), paracentesis directed by ultrasonography may remain an option for those patients. Similar to the FAST examination, ascites is usually diagnosed earliest (even small amounts) in Morison's (hepatorenal) pouch.

# **Preprocedure Patient Preparation**

The patient should be informed about the indications for the procedure as well as the risks and possible complications. The usual risks for paracentesis of solid organ perforation, vascular injury,

**Figure 225-31** Pleural effusion. Note the fluid is above the diaphragm.

bowel perforation, and procedural failure are decreased when ultrasonographic guidance is used. If there is a relative contraindication, the patient should be informed of the increased risk. (See Chapter 201, Abdominal Paracentesis.)

# Technique

- 1. With the patient in the supine or sitting upright position, use a low-frequency probe to scan the usual location for performing paracentesis (in the midline, approximately one-third the distance from the umbilicus to the pubic symphysis, or in a lower quadrant [left usually preferred] about one-third the distance from the umbilicus to the anterior iliac crest). Note the location of any solid organs to avoid. Next, locate the largest, safest collection of fluid for a successful paracentesis. Also, confirm absence of bowel (would be floating in fluid; air in bowel usually causes scatter artifact) and whether the bladder has been emptied adequately. If these conditions are met, perform the procedure in the usual manner.
- 2. For small amounts of fluid, or if there is need for stereotactic paracentesis, perform it under ultrasonographic guidance. Cover the probe with a sterile barrier (e.g., sterile glove) as noted previously for central line insertion. When performing the paracentesis, use the same technique for ultrasonographic guidance as for central line insertion or thoracentesis. In some cases, the echogenic needle may be observed passing into the fluid.

# Interpretation and Results

Peritoneal fluid appears dark or hypoechoic on ultrasonography. Bowel or bladder wall is relatively echogenic. With peritonitis, echogenic objects will occasionally be seen floating in the fluid.

# **OVER-READING SERVICES**

Over-reading services are available through the following websites, among others: www.nighthawkradiologyservices.net and www.radisphere.net.

**NOTE:** These require T1 internet access; DSL is not compliant with the Health Insurance Portability and Accountability Act (HIPAA) Privacy Rule.

# **PATIENT EDUCATION GUIDE**

# FINE-NEEDLE ASPIRATION CYTOLOGY AND BIOPSY

Lee A. Green

Fine-needle aspiration (FNA) and biopsy is a rapid, safe, relatively painless method of sampling solid and cystic masses in a variety of anatomic sites for cytologic examination. Both benign and suspected malignant conditions can be diagnosed with FNA.

Although the procedure is successfully used to sample lesions of the prostate, salivary glands, and intra-abdominal and intrathoracic organs, as well as for culturing cellulitis, the primary care physician will find FNA most useful for masses in the breast and thyroid, and for lymph nodes (especially solitary supraclavicular nodes). For tumors of these sites, positive and negative predictive values for malignancy are typically in the 92% to 98% range, with overall diagnostic accuracy of greater than 70%. However, these rates are highly dependent on the skill of the clinician. It is clear from the literature that FNA should be performed by clinicians who are skilled at technical procedures and well trained in FNA in order to obtain adequate diagnostic accuracy. The availability of a cytopathologist skilled in reading FNA specimens is crucial. Liquid-based cytology (e.g., CytoLyt; Cytec Corporation, Marlborough, Mass) is now standard, obviating the potentially error-prone step of direct slide smear preparation at the time of aspiration.

As implied by the overall diagnostic accuracy rate, as much as one fourth of specimens will return with nondiagnostic results, necessitating repeat aspiration or open biopsy. However, FNA will provide diagnosis in most cases with a procedure that is safer, more comfortable, less invasive, and less costly than open biopsy. These same advantages allow FNA to be used with less hesitation than would open biopsy. For example, many samples can be drawn over time from breast lesions in a patient with fibrocystic disease, whereas repeated open biopsy with subsequent scarring would be unacceptable.

Although false-negative results are generally more common than false-positive results with FNA, the reverse is true for breast aspirations among young women; more than half of all "suspect" FNAs of palpable breast masses among women younger than 30 years of age prove to be benign on excisional biopsy. Fibroadenomas can show cellular atypia, nuclear overlapping, hyperchromasia, and epithelial clustering, and are thus easily overinterpreted.

Some authors advocate use of FNA of breast lesions as one component of a *triple test*, comprising clinical examination, mammography or ultrasonography, and FNA. When all three elements are concordant for malignancy or nonmalignancy, the negative predictive value of the triple test approaches 100%. The majority of the predictive value of the triple test is the FNA result, but attention to a discordance—suspect abnormal clinical and imaging findings with a negative or nonspecific FNA—may help the clinician identify potential false-negative FNAs for further work-up. In the breast, any palpable mass that is new and clinically suspect must be removed if fluid cannot be aspirated, regardless of other test findings.

In all breast complaints, FNA provides significant information. If a mass is palpable, FNA is carried out. If nonbloody cystic fluid is retrieved and the mass is gone, the woman can be reassured of the extremely low likelihood of cancer if the mass does not recur within 6 to 8 weeks. If it does recur, repeat aspiration should be performed. If it recurs a third time, it should be excised. Mammograms are usually done for baseline or confirmation a week after the aspiration.

FNA is widely used for evaluation of thyroid masses, where it has similar predictive values. Nondiagnostic thyroid FNAs prove malignant in approximately 7% of cases. Malignancy is more likely in younger and in male patients, those with high-normal thyroid-stimulating hormone (TSH) levels, and in solitary lesions. Solitary hyperfunctioning nodules with low-normal TSH or patients with more than two nodules are less likely to harbor malignancy. Two successive nondiagnostic FNAs of a thyroid mass should prompt suspicion. More than two FNAs are not generally useful.

#### **INDICATIONS**

- Presence of a palpable, suspect mass in the breast
- Thyroid nodule
- Clinically suspect lymph node or group of nodes
- Any palpable, superficial, nonpulsatile mass

The primary care physician ordinarily does not perform plain radiography—or computed tomography—guided FNA of nonpalpable lesions, but if an office ultrasonography machine is available it can readily be used to guide FNA. FNA is the procedure of first choice, even over imaging studies, for evaluating thyroid nodules and detecting the rare parathyroid tumor.

#### **CONTRAINDICATIONS**

- Unskilled clinician (relative)
- Absence of a cytopathologist capable of proper interpretation of the resulting slides
- Sites of active pyogenic infection, although suspected granulomatous infection (fungal or mycobacterial) of a node does not contraindicate FNA, and FNA can be used (with sensitivity of roughly 20% to 30%) to obtain culture material from cellulitis
- Nonpalpable lesion (unless readily visualized on ultrasonography and office ultrasonography is available)

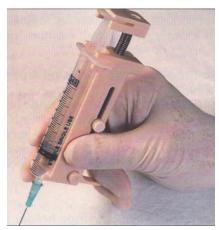

FNA may be performed safely in the anticoagulated patient if studies are in the therapeutic range, with proper attention to compression of the site afterward to avoid hematoma. It may be performed in all but the most severely immunocompromised patients.

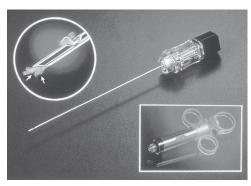

Figure 226-I Breast fine-needle aspiration using Cameco syringe holder.

#### **EOUIPMENT**

- One of the following syringe or needle systems:
  - The syringe pistol shown in Figure 226-1 is available in various sizes from Belpro (Anjou, Quebec).
  - A spring-loaded device called the Tao Aspirator, designed to allow a pencil-type grip on the syringe, is available from Tao & Tao Technology (Camano Island, Wash; Fig. 226-2).
  - Milex Products (Chicago) supplies a breast aspiration biopsy needle (Fig. 226-3), which is unique because of its separate cutting port near the tip.
  - A 21- or 23-gauge butterfly needle can be connected to a syringe. The assistant aspirates the syringe while the clinician manipulates the needle.
  - A 21- or 23-gauge needle can be used on the end of a regular 3-, 5-, or 10-mL syringe.
- Two sterile, plain (nonanticoagulant), evacuated blood tubes.
- 21-, 22-, or 23-gauge needle.
- Syringe of appropriate size.
- 120-mL specimen containers containing 30 mL CytoLyt solution each.
- 4 × 4 gauze pads.
- Sterile gloves.
- Isopropyl alcohol pads or povidone–iodine swabs.
- 1-mL syringe with 30-gauge ½-inch needle (or insulin syringe and needle) and 1% plain lidocaine for anesthesia of skin (optional).

**Figure 226-2 Tao Aspirator.** (Courtesy of Tao & Tao Technology, Camano Island, Wash.)

**Figure 226-3** Milex needle used for needle biopsy. Note the special extra side port to sample more tissue. (Courtesy of Milex Products, Chicago.)

#### PREPROCEDURE PATIENT PREPARATION

Advise patients of the risks and benefits of the procedure, the indications, the alternatives, and the comparative risks and benefits of the alternatives. (See the sample patient education and consent forms online at www.expertconsult.com.)

Significant complications of FNA are rare. A small hematoma or ecchymosis for a few days (especially from thyroid FNA) and some mild soreness are to be expected. The patient must understand that nondiagnostic results occur commonly and may require repeat FNA or open biopsy, and that false-negative and false-positive results are possible. Patients undergoing FNA of breast lesions should wear a supportive brassiere.

#### **TECHNIQUE**

#### **Setup and Preparation**

- 1. Prophylaxis for bacterial endocarditis is not required.
- 2. Prepare the skin with 70% isopropyl alcohol. Povidone–iodine preparation may be used but is not required for FNA. Sterile draping is not required, although neither the needle nor the skin entry site should be touched except with a sterile glove after the skin is prepared.
- 3. Figure 226-4 illustrates the typical equipment setup for FNA. The sterile tray contains both a 5-mL syringe for free-hand aspiration and a 20-mL syringe for use with the aspirator handle; ordinarily one or the other is used, not both. Both 21- and 23-gauge needles are illustrated; either size may be used, although 23-gauge may be preferred in the thyroid and 21-gauge for dense masses and the breast. The 1-mL syringe with a 30-gauge, ½-inch needle may be used for skin anesthesia, if desired. The specimen containers use the same CytoLyt fluid used for ThinPrep-method Papanicolaou (Pap) smears, but it is best to use a container distinct from that used for Pap smears because the laboratory may mistakenly process the FNA specimen as a

Figure 226-4 Setup tray for fine-needle aspiration.

Pap, destroying it. The sterile plain (nonanticoagulant) blood specimen tubes are for cyst fluid, if obtained. Alternatively, the fluid can just be placed in the CytoLyt. If breast fluid is non-bloody (urine colored or green), it does *not* need to be sent to pathology (for cell block, cytology, or anything else) and should be discarded.

4. Skin anesthesia is often not necessary for FNA because the needles are small and not painful. If desired, however, excellent anesthesia can be obtained with 1% lidocaine (plain or with epinephrine) by using a 30-gauge needle on a 1-mL syringe. If the lidocaine is injected slowly and in small volume (approximately 0.5 mL) into the subcutaneous tissues without raising a skin wheal, and then allowed to remain for 5 minutes, anesthesia can be achieved painlessly and without obscuring the lesion to be aspirated. Buffering the lidocaine to near-neutral pH just before injection by mixing it in a 9:1 ratio with 1 mEq/mL sodium bicarbonate solution can further reduce injection discomfort.

#### Sampling

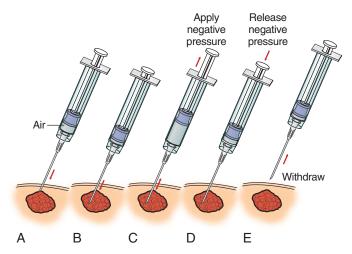

Pneumothorax has been reported with needle aspiration and needle biopsy of the breast. To prevent this, aspirate with the mass positioned over a rib, or keep the needle at a tangential angle as opposed to perpendicular to the body. If the person is thin or the lesion is deep, it may be prudent to have the patient hold her breath while sampling.

Figure 226-5 illustrates the aspiration of a thyroid nodule using one-handed manual withdrawal of the syringe plunger to create vacuum. The fingers hold the plunger while the thumb exerts pressure on the syringe top flange. Figure 226-1 illustrates aspiration of a breast cyst using the syringe holder to withdraw the plunger. Whatever technique is used, the fingers of the nondominant hand stabilize the lesion to be aspirated and provide tactile feedback when the needle has been placed in the lesion.

Before the puncture is made, draw air into the syringe, filling approximately one fifth of its volume. The purpose of this is to have

Figure 226-5 Thyroid fine-needle aspiration using ordinary syringe.

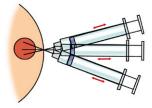

**Figure 226-6** Fine-needle aspiration technique of a solid lesion or cyst (a palpable breast mass, in this case) that remains palpable after fluid has been drained. **A,** Aspirate I to 2 mL of air into syringe before inserting needle. **B,** Insert the needle into the mass and aspirate. If cystic fluid is not obtained or the mass does not resolve, the mass is solid. **C,** Maintain negative pressure in the syringe and move the needle back and forth through the tissue I5 to 20 times to collect cells for analysis (see Fig. 226-7). **D,** Release the plunger. **E,** Withdraw needle and spread contents on a slide, which is immediately fixed

the air to flush out the needle and its contents onto a slide. Without the air, there is no good way to empty the needle. (*Do not* aspirate air after withdrawing the needle from the mass because this will spread the sparse contents all over the inside of the syringe, making it hard to retrieve.) Carefully note the position of the plunger against the syringe markings, and then introduce the needle into the lesion. The standard technique is to then withdraw the plunger to create vacuum and sample the lesion, but recent research suggests that suctionless fine-needle sampling may be equally effective.

Figure 226-6 illustrates the technique of sampling a solid lesion or a cyst that remains palpable after fluid has been drained. Make several (10 to 20) passes into the lesion, filling the needle with cells and sampling all areas of the lesion (Fig. 226-7). Return the plunger to its previously noted resting position before withdrawing the needle from the mass to avoid aspirating the cells into the syringe when the needle is withdrawn. Withdraw the needle from the lesion and skin and use the air that was in the syringe to express the sample from the needle into the specimen container. Aspirate 1 to 2 mL of the liquid cytology solution into the syringe, agitate it gently, and express it gently back into the container. Repeat the procedure if necessary.

If a lesion is cystic and fluid is obtained, draw as much as possible into the syringe. Withdraw the needle and empty the syringe, then perform another aspiration if more fluid remains. Alternatively, detach the needle from the syringe and leave the needle in place, empty the syringe and reattach it, and withdraw more fluid. As

**Figure 226-7** Depiction of how to carry out step **C** in Figure 226-6. The needle is passed multiple times into the mass to obtain adequate sampling.

noted, for nonbloody cystic masses of the breast, the fluid can be discarded and there is no need to send it to pathology.

Fluid obtained from cysts can be placed in liquid cytology solution or submitted in bulk in a sterile tube. (Standard evacuated blood tubes are sterile; those without anticoagulant should be used.) When a breast cyst is aspirated, the fluid should be submitted for pathologic evaluation only if tinged with blood. Yellow or green fluid is diagnostic of benign cysts, and cytology is unnecessary. A sterile tube can also be used to submit semisolid material such as that obtained from a lymph node for culture. If infection is suspected, fluid and solid specimens can be submitted in transport media as well.

#### **POSTPROCEDURE CARE**

Compression of the site with a gauze pad for 5 to 15 minutes will minimize bruising, especially of the highly vascular thyroid area. A compression dressing of folded gauze pads under Elastoplast tape can be applied on suitable sites. In breast biopsies, placement of a stack of folded gauze pads under a snug brassiere forms an effective compression dressing that may be left in place for several hours to prevent hematoma formation. Some physicians apply a small ice pack to the FNA site for 15 to 60 minutes after the procedure.

#### **COMPLICATIONS**

Complications of FNA are limited primarily to *diagnostic failure* or to false-negative and false-positive results. The incidence of failure is strongly dependent on the operator. *Minor hematoma* formation is a frequent occurrence but is seldom of clinical significance. *Pneumothorax* has been reported in rare instances. Before the wide-spread use of FNA, concern was often expressed about the possibility of seeding the needle track with malignant cells or releasing malignant cells to spread through lymphatics. Neither of these theoretical complications has been documented to occur, and they should not be considered complications of FNA. *Damage to local anatomic structures* (e.g., recurrent laryngeal nerve injury with thyroid FNA) is possible but occurs rarely; most large case series have not reported such injuries. The lack of complications is probably due to the small diameter of the needles used for FNA, in contrast to cutting-needle biopsies, which do cause injury with some frequency.

## HEIMLICH MANEUVER

Raymond F. Jarris, Jr.

Each year in the United States, 3000 people die from swallowing or aspirating objects. When a patient displays the distress signal for choking (i.e., clutching the neck) or becomes cyanotic, unconscious, or unable to cough or breathe effectively (suggesting complete obstruction), efforts to clear the obstruction are warranted. The Heimlich maneuver (abdominal thrusts) causes a sudden increase in intrathoracic pressure, forcing an obstructing object from the glottis (Fig. 227-1).

NOTE: In the event of partial foreign body aspiration, if the patient is able to move air or speak, the Heimlich maneuver and probing of the oropharynx should be avoided and the patient should be transported to a source of emergency medical care.

#### **INDICATION**

Asphyxiation from a foreign body obstruction of the upper airway indicates treatment. If forceful coughing is occurring, do not interfere with the coughing. However, the Heimlich maneuver is indicated if the cough becomes silent, respiratory difficulty increases and is accompanied by stridor, or the victim becomes unresponsive. In the unresponsive patient, a "finger sweep" of the posterior oropharynx should only be used when the provider can see solid material obstructing the airway.

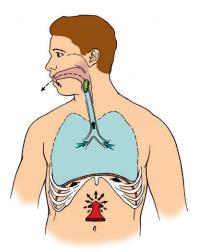

Figure 227-1 The Heimlich maneuver causes a sudden increase in intrathoracic pressure, forcing an obstructing object from the glottis. If the patient is sitting or standing, the clinician should stand behind the patient and wrap his or her arms around the patient's waist. The clinician's fist should be placed with the thumb side against the patient's abdomen, above the umbilicus but below the rib cage.

#### **CONTRAINDICATIONS**

The Heimlich maneuver is contraindicated in infants, small children, and pregnant women (abdominal thrusts inappropriate). It may also be difficult to accomplish in obese patients if the clinician is unable to encircle the victim's abdomen. In obese patients and in pregnant women, chest thrusts may be appropriate.

#### **TECHNIQUE**

#### Adults and Children Older Than I Year of Age Sitting or Standing

Apply three to five abdominal or chest thrusts (Fig. 227-2A). These thrusts lift the diaphragm and force enough air from the lungs to create an artificial cough to move and expel an obstructing foreign body in an airway.

#### Lying

- 1. Place the patient in the supine position.
- 2. Place one hand on top of the other, with the heel of the bottom hand positioned in the midline of the patient, between the umbilicus and xiphoid.
- 3. Lean forward with shoulders over the patient's abdomen and quickly press inward and upward three to five times (Fig.
- 4. In pregnant or obese patients, use chest thrusts delivered in the same fashion as step 3, but place hands over the sternum.
- 5. Clear visible material from the oropharynx with a finger sweep or Magill forceps.

#### Infants to I Year of Age

- 1. Place the child face down on your arm with head directed downward, supporting head and neck with knee and one hand (Fig.
- 2. Deliver three to five gentle back blows between the scapulae with the palm of the hand.
- 3. If obstruction is still present, roll the child over, lower his or her head, and deliver chest thrusts gently with two to three fingers as in cardiopulmonary resuscitation.
- 4. Repeat steps 2 and 3 until the object is cleared or surgical intervention is required (see Chapter 199, Cricothyroid Catheter Insertion, Crycothyroidotomy, and Tracheostomy).

#### COMPLICATIONS

- Abdominal aortic aneurysm thrombosis
- Internal carotid artery dissection
- Esophageal rupture
- Gastric rupture
- Jejunal rupture
- Liver, spleen, or pancreas injury

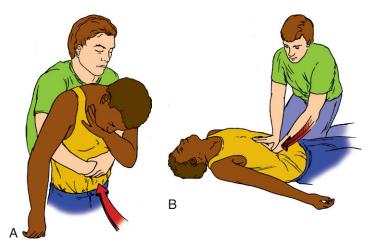

Figure 227-2 Abdominal thrusts. **A,** If the patient is sitting or standing, the clinician should stand behind the patient, wrap his or her arms around the patient's waist, grasp the fist or wrist of one hand with the other, place the hands against the patient's abdomen between the navel and rib cage, and press the fist into the patient's abdomen with a quick thrust upward. This should be repeated up to three to five times. **B,** If the patient has collapsed or is unable to be lifted, he or she should be placed in the supine position and the clinician should kneel beside the patient's abdomen or straddle it. The clinician should place one hand on top of the other, with the heel of the bottom hand in the midline between the patient's navel and rib cage. He or she should lean forward so that the shoulders are over the patient's abdomen and press toward the diaphragm with a quick thrust, inward and upward. The clinician should not press to the right or left of the midline. This should be repeated up to three to five times if necessary.

- Pneumomediastinum
- Regurgitation
- Rib fracture

The Heimlich maneuver is usually performed outside of medical facilities. Although complications are rare, most of the complications are severe and can be life-threatening. For example, gastric rupture has a high mortality rate. A physician should evaluate all persons who have been subjected to the Heimlich maneuver. Focused evaluation by the physician should include history and physical examination of the respiratory and gastrointestinal system. Early intervention may reduce the morbidity and mortality associated with these complications.

Figure 227-3 Back blows for infants and small children. See text for details.

## MUSCLE BIOPSY

James R. Shepich

Many disorders of the motor unit can be identified by clinical presentation, but occasionally a muscle biopsy is necessary for diagnosis. Muscle biopsy is a relatively straightforward procedure that may be performed under local anesthesia. However, many authorities contend that a better-quality specimen can be obtained under general anesthesia because injudicious local infiltration can affect the histology. The site of biopsy and the type of biopsy (open vs. core needle) vary with the patient and disease.

The *muscle of choice* should show the effects of the disease process. However, the most severely affected muscles *should be avoided* because the muscle mass may be replaced by scar tissue or fat, and an adequate pathologic diagnosis may not be possible. Muscles with recent trauma, including recent electromyography (EMG) or infection, should not be sampled. Muscle in areas of tendinous transition should be avoided because the increased connective tissue may be mistaken for fibrosis during pathologic assessment. Some commonly sampled muscles include the lateral aspect of quadriceps femoris, deltoid, biceps brachii, tibialis anterior, and gastrocnemius.

The biopsy method depends on clinical judgment. Core needle biopsy is less invasive and causes less pain and scarring than open biopsy. It is easier to perform, especially in children, and allows repeat biopsy of the same muscle if necessary. Open biopsy allows a larger specimen to be taken, which increases the chance of definitive diagnosis and allows multiple modalities of pathologic preparation of the specimen if needed, including electron microscopy. Open biopsy is also ideal if disease of the motor end plate is suspected. With either approach the muscle to be sampled should be placed in an extended, relaxed position.

#### **INDICATIONS**

A muscle biopsy is performed to identify syndromes of muscle weakness that do not present with classic findings. Several diseases, such as Duchenne's muscular dystrophy, Werdnig-Hoffmann disease, and myasthenia gravis, have classic presentations and muscle biopsy is not necessary. Muscle biopsy can be used to distinguish between neurogenic and myopathic processes, identify congenital myopathies, and diagnose connective tissue disorders and muscle infections, such as trichinosis and toxoplasmosis. Metabolic disorders of the muscle may also be found by biopsy. Biopsy is also indicated in the identification and indexing of hereditary disorders.

#### **CONTRAINDICATIONS**

- Anticoagulation and bleeding disorders
- Recent trauma of the muscle, including EMG
- Clinical appearance of Duchenne's muscular dystrophy (biopsy can cause scarring and contracture of muscle)
- Infection in region of proposed biopsy

#### **EQUIPMENT**

#### **Open Biopsy**

- Sterile drapes
- Povidone–iodine
- Local anesthesia (1% lidocaine without epinephrine)
- Scalpel with no. 11 or no. 15 blade
- Forceps, iris scissors, suture scissors
- 3-0 Vicryl or Monocryl sutures
- 4-0 Vicryl or Monocryl sutures
- Electrocautery or diathermy (not to be used until after biopsy sample is procured)
- 4 × 4 gauze sponges
- Tongue blade, cut into 6- to 7-cm lengths, with V-groove in ends, or 22-gauge needles to pin specimen
- 3-0 nylon or Prolene suture
- Steri-Strips, Tegaderm, Op-Site, or dressing of choice

#### **Core Needle Biopsy**

- Sterile drape
- Povidone–iodine
- Local anesthesia
- Tru-Cut, Biopty, Conchotome, or equivalent needle
- Band-Aid

#### PREPROCEDURE PATIENT PREPARATION

The patient should be informed that the procedure is relatively painless, but that the biopsy site may be sore for several days. Many patients experience a sensation of muscle bruising and occasionally a pulling sensation. The patient does not need to restrict food and fluids before the procedure, but he or she should be instructed to wear loose-fitting clothes that readily allow access to the intended biopsy site. Little postprocedural disability or recovery time is expected and the patient may return to usual activity immediately. Analgesic medication is rarely needed, and when it is necessary, it is usually only for 24 to 48 hours. Risks, benefits, and potential complications should be discussed with the patient before the procedure (see the sample patient education handout online at www.expertconsult.com).

#### **TECHNIQUE**

#### **Open Biopsy**

The patient should be prepared and draped, with the muscle in an extended, relaxed position. To prevent a vasovagal episode, the patient should be lying down. The *skin* overlying the muscle to be

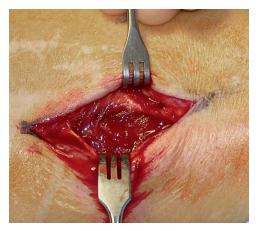

Figure 228-I Incision for biopsy of rectus femoris muscle.

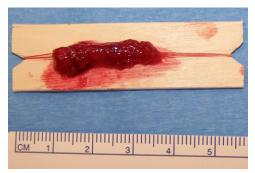

sampled is infiltrated with local anesthesia. Care should be taken to avoid infiltration of the muscle itself. A 3- to 4-cm incision is made over the muscle belly, in an axial orientation to the muscle (Fig. 228-1). The skin and subcutaneous tissue are retracted and the fascia exposed. The fascia is opened sharply in a longitudinal fashion, and the muscle is exposed. Care should be taken to avoid injuring cutaneous nerve branches, which often lie on the fascia. A portion of muscle approximately 3 to 4 cm in length and 5 mm in diameter is excised after a nonabsorbable suture is placed at each end. The excisional sites are "outside" of the sutures. The specimen is maintained in an extended state and transferred to the tongue depressor, where the suture can be placed in a V-groove on either end or pinned to the surface with 22-gauge needles (Fig. 228-2). Hemostasis is achieved with diathermy or electrocautery.

Many pathologists require two specimens for a muscle biopsy. The first is a piece of muscle measuring 0.5 to 1 cm, and the second is an additional fascicle 2 to 3 cm in length and 5 mm in diameter that is tied to a splinter of tongue blade in situ, before it is excised (Figs. 228-3 to 228-5).

The fascia is then closed with 3-0 Vicryl sutures to prevent muscle herniation. The skin is closed with a running subcuticular stitch. Steri-Strips and a sterile dressing are applied. Dermabond or other skin adhesive may also be used.

#### **Core Needle Biopsy**

The patient is prepared, draped, and anesthetized as previously described for an open biopsy. A small nick is made in the skin with a no. 11 blade, and the bioptome is introduced. Care should be taken that the throw of the needle does not carry it into vital structures or bone. The bioptome is then activated. Multiple passes may be taken through the muscle in different areas, and usually three cores

**Figure 228-2** Muscle portion approximately  $1 \times 1 \times 2$  cm stretched on a tongue blade.

Figure 228-3 Muscle fascicle tied in situ to splinter of tongue blade.

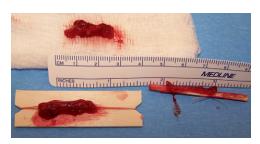

of tissue are obtained. Pressure is held at the site for 2 to 3 minutes, and a Band-Aid is then applied.

#### **COMPLICATIONS**

Potential complications include bleeding, hematoma, or bruising at site of biopsy. The wound may become infected or be slow to heal, especially in patients with connective tissue disorders who have been on steroids. In some conditions biopsy may lead to fibrosis and contracture of the muscle. Mild postprocedural discomfort is usual, and prolonged paresthesia can be experienced if a sensory nerve is injured. Also, the biopsy may be nondiagnostic, requiring a repeat biopsy.

## HANDLING OF TISSUE AND INTERPRETATION OF RESULTS

Note the muscle sampled for the pathologist. (The deltoid muscle has an unusual connective tissue pattern that may be misinterpreted.) Other information supplied to the pathologist should include a clinical summary of symptoms and their distribution and duration. The results of EMG, nerve conduction velocity, and pertinent laboratory studies should also be included. Muscle biopsy should be performed in coordination with a pathologist because the specimen should never be placed in a fixative and should be processed within 30 minutes of its removal. A longer interval will cause specimen desiccation and architectural distortion. Standard pathologic assessment includes sectioning after cryostat freezing of the specimen, electron microscopy, and immunohistochemical analysis. The pathologic diagnosis is based on the architecture of the muscle group, the characteristics of the individual fibers, and the presence of increased connective tissue or inflammatory cells. Electron microscopy will reveal abnormalities of the mitochondria and other cellular infrastructure. Special staining for oxidative, glycolytic, and hydrolytic enzymes will add information about enzyme deficiency, inflammation, and mitochondrial and lysosomal abnormalities. Stains with periodic acid-Schiff reagent and Oil Red O will help diagnose glycogen and lipid storage disorders. Immunohistochemical assay will add information regarding dystrophin, major histocompatibility complex receptors, and autoimmune disorders.

**Figure 228-4** Three specimens for histology, immunochemistry, and electron microscopy.

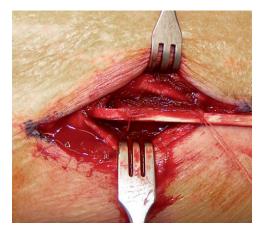

Figure 228-5 Technique for in situ harvest of muscle fascicle.

#### **POSTPROCEDURE PATIENT EDUCATION**

The patient should be instructed to monitor the area of biopsy for signs or symptoms of infection, excessive bleeding, or hematoma formation. A small amount of serosanguineous fluid may accumulate beneath the dressing. The outer dressing should be maintained for at least 48 hours and then removed. The Steri-Strips may be removed between the fifth and seventh days after the biopsy (see the sample patient education handout online at www.expertconsult.com).

# Transcutaneous Electrical Nerve Stimulation, Phonophoresis, and Iontophoresis

Russell D. White • Mary Beth Brown

The procedures described in this chapter—transcutaneous electrical nerve stimulation (TENS), phonophoresis, and iontophoresis—can be performed either by primary care clinicians in their office or by physical therapists when ordered by a clinician. The procedures are often used with other physical therapy modalities such as manual therapy or therapeutic exercise. The choice of procedure depends on the size (localized vs. diffuse) and depth (superficial vs. deep) of the proposed treatment area as well as the specific pathologic process.

#### **EQUIPMENT**

- Scissors to trim hair
- Isopropyl alcohol 70% to cleanse skin
- For TENS: TENS unit with either disposable or reusable electrodes and gel
- For phonophoresis: therapeutic ultrasound unit, appropriate medication, and coupling gel
- For iontophoresis: direct-current generator with constant current output (calibrated in milliamperes), electrodes, and appropriate medications

#### PREPROCEDURE PATIENT PREPARATION

After discussing the patient's diagnosis, the risks and benefits of the selected treatment should be explained, along with any treatment options. Oral or written consent should be obtained from the patient. Patients should be aware that their skin will be cleansed and that their hair may be trimmed. The anticipated treatment plan and total number of treatments should also be discussed.

## TRANSCUTANEOUS ELECTRICAL NERVE STIMULATION

Transcutaneous electrical nerve stimulation therapy uses low-voltage electrical pulses to stimulate the nervous system and is used for the treatment of pain syndromes. Skin surface electrodes are used to pass the electricity into the affected area. TENS units are Class II, U.S. Food and Drug Administration—approved devices and are typically selected for larger, generalized areas of pain, for chronic joint pains, or for persistent myalgias. This procedure can be performed in the clinician's office and is reimbursable if performed by the clini-

cian. However, TENS therapy is usually prescribed by a clinician and performed by the physical therapist. When prescribed for home use, the patient must be competent in operating a TENS unit.

TENS therapy is based on the *gate theory of pain*. According to this theory, nociperception (injury information) is transmitted through T cells that convey information to the higher brain centers. This information is presynaptically inhibited by interneurons in the substantia gelatinosa. TENS therapy bombards these interneurons, attempting to modulate or decrease the pain transmission by effectively blocking transmission of pain sensation. Other theories suggest that TENS therapy achieves its result by an acupuncture effect, by release of natural opiates, or by direct local vasodilation, which may reduce relative ischemia.

The goal of TENS therapy is to reduce or relieve pain and discomfort. This result may be either short lived or prolonged. TENS therapy may slowly break the *pain-spasm-pain cycle* and reduce perceived discomfort. Unfortunately, TENS therapy is not effective for pain of central origin (e.g., headache).

Treatment parameters are chosen based on several factors:

- Intensity: Small unmyelinated fibers require more current than large myelinated fibers. (Intensity is set according to patient comfort [strong but not painful] and can vary widely by body part undergoing treatment, by device used, and by individual sensation and tolerance.)
- Pulse rate: Small unmyelinated fibers respond better to a low-frequency rate (<100 Hz), whereas large myelinated fibers respond better to a high-frequency rate (>100 Hz).
- Wave characteristics: These characteristics are either monophasic (positive rectangular pattern) or biphasic (negative spike pattern).
- Pulse width: Small unmyelinated fibers respond to a long pulse (200 milliseconds [msec]), whereas large myelinated fibers respond to a short pulse (50 msec).
- Modulation: Modulation allows gradual variation of the frequency or pulse width and retards accommodation of the nervous tissue.

#### **Indications**

- Chronic pain
- Acute pain
- Musculoskeletal pain
- Neurologic pain (e.g., herpes zoster)
- Phantom limb pain

- Before another procedure to elevate the pain threshold and to decrease patient discomfort after the procedure
- Postoperative pain
- Obstetric pain (after the first trimester)

#### **Contraindications**

- Patients with demand-type pacemakers (Newer pacemakers with improved shielding are not affected by TENS units. Check with a cardiologist or the manufacturer.)
- Patients in first-trimester pregnancy
- Patients with known cardiac dysrhythmias
- Mentally incompetent patients, uncooperative patients, those with paranoid disorders, or pediatric patients without adult supervision
- Undiagnosed pain syndromes without established etiology
- TENS therapy is also contraindicated over the following areas:
  - Carotid sinuses
  - Chest areas in patients with a cardiac history
  - Head or neck area of patients with an epileptic history
  - Laryngeal or pharyngeal muscles
  - Local areas of skin irritation or loss of skin integrity
  - Mucosal surfaces
  - Eyes

#### **Technique**

- Before initiating therapy, organize the necessary materials (Fig. 229-1) and prepare the skin area to which the electrodes will be attached. Trimming hair and cleansing the skin with 70% isopropyl alcohol will promote the adhesion and conductivity of the electrodes.
- 2. Select the proper electrodes. For 24 hours or more of use, select either a carbon-impregnated rubber electrode with gel or a carbon-filled silicone electrode.
- 3. Attach electrodes to the selected treatment site, whether isolated trigger points, individual dermatomes or myotomes, or in the distribution of a specific nerve. Position the electrodes so that a paresthesia will be felt in the area of pain or dysfunction (Fig. 229-2). If the electrodes are secured poorly to the skin, they may cause a burning sensation instead of a paresthesia. In addition, electrodes should be placed at least 2 inches apart. Placing electrodes closer together can cause a burning sensation. The electrodes should also be placed so that the perimeter of the painful area is entirely surrounded by the electrodes.

**Figure 229-1** Transcutaneous electrical nerve stimulation (TENS) unit (generator) with supplies for skin preparation, electrodes, and electrode wires.

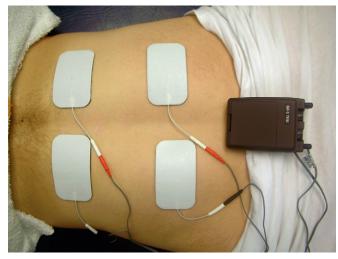

Figure 229-2 TENS treatment.

- 4. Select the treatment parameters. Conventional settings use a high-frequency rate with a narrow pulse width. The intensity level is *less than* that which results in muscle stimulation.
- 5. With the amplitude control in the off position, attach wires to the TENS unit. Turn on the generator unit and increase the amplitude slowly, up to the patient's comfort level. Again, paresthesia should be felt by the patient before the threshold for motor stimulation.
- If desired results (paresthesia with control of pain) are not achieved, change the stimulation sites or adjust the treatment settings.
- 7. Typically, patients are treated once or twice daily for a duration of 30 to 60 minutes. Some patients may benefit from more frequent treatments and may require a home unit for therapy.
- 8. When the treatment is completed, turn off the unit, return the settings to zero, and remove the electrodes.

#### **Complications**

- Skin irritation from electrode placement
- Contact dermatitis resulting from electrode gels
- Pacemaker malfunction (typically an older pacemaker)
- Twitch response secondary to stimulation of a motor nerve or end plate in the treatment area by inappropriate current

#### **PHONOPHORESIS**

Phonophoresis uses therapeutic ultrasound to enhance the diffusion of medications across the skin and into body tissues. Commonly used medications include dexamethasone, hydrocortisone, and lidocaine. Although phonophoresis is usually performed by the physical therapist, some clinicians provide this modality in the office setting. Clinicians can be reimbursed for phonophoresis, even if not performed by a physical therapist.

The dual action of phonophoresis—thermal and mechanical—counteracts the inflammatory response by a process called *acoustic streaming*, which increases cell membrane permeability. This effect also facilitates the passage of medications into body tissue. With *acute* inflammation, using pulse-mode ultrasound avoids an increase in tissue temperature. In addition to the alteration of tissue permeability, beneficial effects are obtained through nonthermal changes (e.g., stimulation of fibroblasts). With *chronic* inflammation, using continuous or nonpulsed ultrasound can produce thermal changes that counteract or prevent the chronic changes of scarring and tissue edema.

Ultrasound dose is measured in intensity (intensity =  $W/cm^2$ ), which is the acoustic energy delivered through the surface area of the head of the transducer. Areas of inflammation are usually treated with 1 to 2  $W/cm^2$  for 5 to 10 minutes. Results are measured by the improvement (either immediate or gradual) in pain or function of the treated area.

#### **Indications**

- Superficial periarticular disorders: bursitis, tendinitis, ligament sprains
- Contracture of joint capsules or adhesive scars
- Neuromas
- Reflex sympathetic dystrophy
- Plantar warts
- Muscular strains, fibrosis, spasm, myositis (limited evidence)

#### **Contraindications**

- Allergy to medications being used
- Tumors
- Thrombophlebitis
- Pregnancy (therapeutic ultrasound is contraindicated over the abdomen and pelvis)
- · Hemorrhagic or infected areas
- Cardiac disease (therapeutic ultrasound over the cervical ganglia, cardiac area, or an implanted pacemaker may produce a detrimental cardiac reflex)
- Unhealed fracture sites
- Phonophoresis should also be avoided over the following areas:
  - Epiphyseal plate in growing bones
  - Spinal cord
  - Area of previous radiation therapy (wait 6 months before applying ultrasound)
  - Eyes

#### **Technique**

- 1. A clinician's prescription is required for the medications when phonophoresis is administered by a physical therapist.
- 2. Select an area of inflammation for treatment that is no greater than twice the surface area of the sound head.
- 3. Select the proper ultrasound equipment (Figs. 229-3 and 229-4).
- 4. Cleanse the general area to be treated. Inspect the skin for excessive dryness and trim excess hair. Skin areas may be pretreated

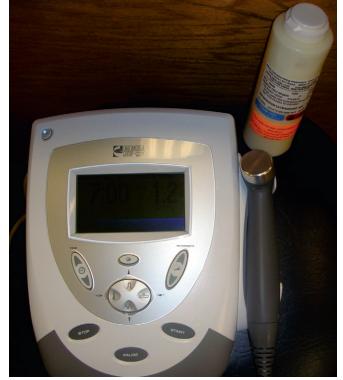

Figure 229-4 Ultrasound unit.

- with moist heat packs to facilitate drug absorption by dilating the hair follicles.
- 5. Because the chosen agent can affect ultrasound transmission, select only topical agents that transmit ultrasound. (Hydrocortisone 10% or ketoprofen 2.5 % in an aqueous base are commonly used medications for phonophoresis.) Apply the medication followed by the coupling gel or use coupling gels impregnated with medication.
- Apply phonophoresis through the sound head in a moving pattern of overlapping strokes or circles (Fig. 229-5).
- 7. Recommended *intensities* of 1 to 2 W/cm<sup>2</sup> usually provide effective results. Use *frequencies* of 3 MHz for superficial tissues and 1 MHz for deeper tissues. Apply for 5 to 10 minutes. Treatment

**Figure 229-3** Ultrasound–electrical stimulation combination unit used for phonophoresis and TENS.

Figure 229-5 Phonophoresis treatment.

- for greater than 10 minutes increases the risk of a negative effect (e.g., periosteal burn).
- 8. When finished, wipe away coupling gel but do not cleanse skin; there is some evidence that an occlusive dressing may further promote continued medication absorption.

#### **Complications**

- Previously unknown allergy or sensitivity to medication
- Systemic side effects from excessive absorption of applied medication
- Damage to susceptible areas (listed in Contraindications section)

#### **IONTOPHORESIS**

Iontophoresis uses direct electrical current to enhance the diffusion and absorption of charged medications across the skin and mucous membranes. With this technique, medicinal ions can penetrate tissue for 0.2 to 1.5 cm, depending on the drug used and the characteristics of the local tissue. This technique is based on repulsion of similarly charged ions; charged ions in solution are driven away from like-charged electrodes.

Iontophoresis works best when the pathologic process is superficial and localized. This treatment is usually performed in an outpatient rehabilitation setting or in the clinician's office. Primary care clinicians can be reimbursed for the procedure, even if it is not performed by a physical therapist.

The most common *medications* used are dexamethasone or lidocaine and the amount depends on the size of the treatment area. The amount used also depends on the electrode size and the volume it takes to fill it. Electrode size varies from 1.5 to 3.5 cm<sup>3</sup>. Dexamethasone is the primary agent indicated for inflammatory lesions. Lidocaine is the agent typically used for preoperative topical anesthesia.

The *electrical* dose for administration is expressed in milliampere minutes (mA minutes) and is the product of the *intensity* (milliamperes) and *duration* (minutes). Most treatments last 10 to 20 minutes each and are repeated three to eight times (depending on patient response).

#### **Indications**

- Same indications as for a superficial injection of a therapeutic agent (superficial, because the medications *penetrate* only up to 1.5 cm with iontophoresis)
- Inflammation
  - Bursitis
  - Tendinitis
  - Fasciitis
  - Sprain
  - Strain
  - Trigger points
  - Carpal tunnel syndrome
  - de Quervain's disease
- Analgesia
  - Neuritis
  - Local anesthesia for invasive procedures, such as dermatologic procedures
- Other (limited case reports; Table 229-1)
  - Ganglion
  - Hyperhidrosis of feet or palms
  - Ischemic ulcer
  - Neuroma
  - Post-traumatic edema
  - Scar tissue
  - Tinea pedis
  - Turf toe
  - Warts
  - Wound healing

<b>TABLE 229-1</b>	Indications	and	Dosages	for	Common
lontophoresis	s Agents				

Ion (Dose)	Polarity	Therapeutic Use
Acetic acid (3–4 mA × 10–20 min)	Negative	Calcified tendinitis, calcium deposit
Chloride, sodium (4 mA × 20–45 min)	Negative	Keloids, scar tissue
Copper sulfate (4 mA × 20–30 min)	Positive	Fungal infection
Dexamethasone (I-4 mA × 15-20 min)	Negative	Tendinitis, tenosynovitis, bursitis, arthritis
Hyaluronidase (1–2 mA × 20–40 min)	Positive	Edema, lymphedema, scleroderma
lodine (2 mA × 1 min; then 4 mA × 5 min)	Negative	Fibrosis, scar tissue, trigger finger
Lidocaine 4% (4 mA × 20–30 min)	Positive	Skin anesthesia
Methylprednisolone (1–4 mA × 15–20 min)	Negative	Postherpetic neuralgia
Salicylate (4 mA × 45 min)	Negative	Analgesia, myalgia, plantar warts
Zinc (4 mA $\times$ 15 min)	Positive	Wound healing, ulcers

#### **Contraindications**

- Allergy or sensitivity to therapeutic agent
- Patients with pacemakers because electric current could interfere with sensitive implanted devices
- Iontophoresis should also be avoided over the following areas:
  - Areas of abnormal skin sensation (patients must be able to give feedback so that the intensity can be set correctly)
  - Superficial abrasions, cuts, and bruises
  - Areas of recent bleeding
  - Areas surrounding or superficial to an implanted or embedded wire, screws, staples, or other metallic objects
  - Recent scars or skin graft
  - Area over heart
  - Area over carotid sinus

Areas of abnormal sensation or a loss of skin integrity have decreased skin resistance; this raises the risk that an increased current dose may be given. Such a dose may lead to undesired skin reactions. Areas of increased vascularity or those near metal objects can also be subjected to enhanced current dosage.

#### **Technique**

- A clinician's prescription is required for the medications administered by a physical therapist using iontophoresis.
- Position the patient to obtain good exposure for the area to be treated. Inspect the skin of the treatment area for any recent injury or any contraindications previously listed.
- 3. Clip excessive hair but do not shave. Clean the skin treatment area with 70% isopropyl alcohol to remove surface oils and skin cells
- 4. Before initiating therapy, the clinician should organize the equipment and select a direct-current generator (Fig. 229-6). Next, inject the premeasured medication into the electrode reservoir according to the manufacturer's recommendations. (Properly filling electrodes to specified volumes decreases skin irritation.)
- 5. The active electrode (drug containment electrode) should be attached over the treatment area. It should have the same polarity as the medication to be used. Attach the larger dispersive electrode (indifferent electrode) over an area that is at least 3 inches distant (Fig. 229-7) from the active electrode.
- 6. Connect the electrode leads to the current generator. Current settings should range from 0.1 to 4 mA.

**Figure 229-6** Iontophoresis current generator with iontophoresis agent, measuring syringe, alcohol wipe for skin preparation, electrodes, and electrode leads.

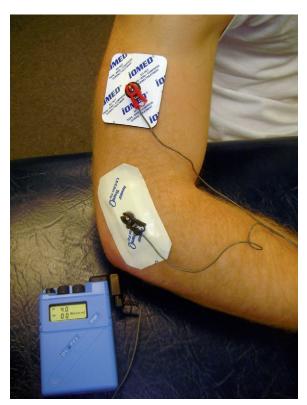

Figure 229-7 Iontophoresis treatment.

- 7. Determine the current dosage on the basis of the diagnosis and treatment. The recommended dosage for dexamethasone or lidocaine is listed in Table 229-1 and measured in mA × min. (milliamperes [current] × minutes [time] = mA × min [dosage]).
- 8. Gradually increase the current until the patient barely feels it. Any sudden change in current may produce burning, stinging, or a twitch response. With most units, the treatment time is automatically set by the device once the intensity (current) and dosage are determined and entered.
- 9. During and after the procedure, ask the patient every 2 to 4 minutes if he or she is experiencing any adverse effects.
- 10. When the procedure is completed, remove the attached electrodes. Instruct the patient to report any delayed adverse effects. (Post-treatment erythema is common, resulting from either changes in skin pH or a histamine reaction.)
- 11. An alternative, recently developed technique is the use of a wearable, battery-powered iontophoresis patch. The patch is filled with medication by a physician or a physical therapist in the clinic and applied directly to prepared skin. Medication is iontophoretically delivered using a constant 0.06- to 0.45-mA current over 3 to 24 hours (varies by manufacturer) with automatic current shut-off when desired dosage is reached.

#### **Complications**

- Previously unknown drug allergy or sensitivity to medications
- Galvanic rash: hypersensitivity reaction to the direct current that develops within 5 minutes of initiating the electrical stimulation
- Twitch response secondary to stimulation of a nerve in the treatment area by inappropriate current
- "Negative electrode burn": skin burn resulting from a decrease in skin resistance and an alkaline reaction when the negative electrode (cathode) is the active electrode (newer electrodes stabilize the pH better and cause less skin irritation)
- Local immunologic inhibition from the steroid (dexamethasone is not detected in the bloodstream after treatment)

## POSTPROCEDURE PATIENT CARE AND EDUCATION

The patient's results are evaluated by determining the decrease in pain or inflammation after treatment(s). Treatment(s) can be terminated when the patient has reached the desired clinical goal. The number or frequency of treatments can be increased to improve the results, as long as no adverse effects have been noted. On the contrary, after five treatments with any of these modalities, if there are no results, another type of therapy should be considered.

The patient should know to report any delayed adverse reactions to the clinician. He or she should also know when to make a follow-up appointment.

## PREOPERATIVE EVALUATION\*

Maury J. Greenberg

The preoperative medical consultation may be one of the most misunderstood services provided by primary care clinicians. Often incorrectly referred to as a "clearance," it is more properly a consultation provided by the patient's primary clinician, at the request of the operating surgeon. The goal of this consultation is to assess the patient's medical condition to minimize risks of untoward events related to the proposed surgical intervention.

In some instances, the operating surgeon is also the primary care clinician, in which case the preoperative evaluation may be conducted as part of the overall decision-making process surrounding the need for an office- or hospital-based diagnostic or therapeutic procedure. In others, the consultation may be performed before surgery by another clinician. In either case, it provides an opportunity for the primary care clinician to review the patient's overall health status and bring up to date a variety of issues such as recommended screening tests, medication adjustments, and lifestyle modifications. It may also afford an opportunity to review previously offered recommendations the patient has failed to pursue, such as screening colonoscopy, smoking cessation, weight loss, vaccination, or, in the case of children, developmental assessments.

As a consultation, the results must be reported to the requesting surgeon in a timely fashion and in a usable format, and must include clear, concise, and specific recommendations related to the proposed surgical procedure.

It should also be noted that, particularly in the case of procedures performed in hospitals, the preoperative evaluation will become a part of the patient's medical record. As such, should complications arise or unexpected events occur, this evaluation may provide the only comprehensive medical history immediately available.

Finally, it must be recognized that "standards" change. Ongoing research and evidence results in changes to our understanding of what is best for optimizing a patient's condition and to limit risks. For example, changes to American Heart Association guidelines for prevention of bacterial endocarditis (www.americanheart.org) have altered the use of preoperative antibiotic prophylaxis in many patients. It is important, therefore, for every clinician to maintain access to current guidelines and to seek expert consultation when indicated.

#### **SURGICAL RISK**

Determining the relative risk of a given procedure must take into account the patient's underlying condition, the specific risks of the procedure itself, the risks of anesthesia, and the possibility of post-operative complications. In most cases, "risk" refers to the possibility of cardiovascular complications in adults or respiratory complications in children. However, in the face of underlying conditions

such as bleeding disorders, asthma, steroid dependence, or renal insufficiency, an otherwise simple procedure can present risks that require careful preoperative preparation. The timing of an elective procedure can also modify the risk, particularly during the postpartum period, or in a patient with a recent myocardial event such as an infarction.

#### **Risk from Procedures**

- High-risk procedures (often >5% risk) include cardiac procedures, aortic and other major vessel vascular procedures, and peripheral arterial procedures.
- Intermediate-risk procedures (1% to 5% risk) include intraperitoneal, intrathoracic, carotid or aortic stent, carotid endarterectomy, orthopedic, head and neck, and prostate procedures. Although each of these types of surgery may entail specific risks such as anticipated blood loss, risk of airway compromise, or risk of intraoperative or postoperative neurologic complications, they are not unanticipated and are addressed by the operating surgeon together with the anesthesiologist as part of the operative plan.
- Low-risk procedures (<1% risk) include cataract surgery, most endoscopic procedures, and breast, superficial skin, and ambulatory noncardiac surgeries.

Most office-based procedures such as skin biopsy, colposcopy, vasectomy, and others that require no anesthesia or only topical or local anesthesia do not increase the risk of cardiac or pulmonary events in otherwise healthy individuals and are considered low risk. Such procedures, including dental procedures performed with self-administered 50% nitrous oxide and other diagnostic or therapeutic procedures performed without sedation or analgesia, do not usually require a separate or specific preoperative consultation, especially if the procedure is performed by the patient's primary care clinician, who is familiar with the individual's medical history.

#### **Patient Risk Factors**

Risk is further determined by considering the patient's medical conditions, including that which resulted in the need for surgery. Clinical predictors of increased risk of cardiac complications associated with surgery include uncontrolled coronary occlusive disease including unstable angina, uncontrolled congestive heart failure, significant valvular disease (especially aortic or mitral stenosis), recent (<30 days) myocardial infarction, and cardiac dysrhythmias associated with hemodynamic instability.

Concurrent medical conditions, including uncontrolled hypertension, diabetes, obstructive pulmonary disease (asthma or emphysema), poor nutritional status, bleeding disorders, hypercoagulable states, ischemic cerebrovascular disease, liver disease, kidney disease, or immune deficiency, will also require assessment and specific interventions to reduce risk, if possible.

In some cases, the decision may need to be made that an elective procedure should be deferred until risk factors have been fully evaluated and appropriate interventions performed.

<sup>\*</sup>The opinions contained in this chapter are solely those of the author and do not represent the official policy or doctrine of the Department of Defense, the U.S. Public Health Service, or the Uniformed Services University of the Health Sciences.

Although it may be intuitive to assign greater risk of a given procedure to patients of advanced age, there is no evidence for age as an independent variable correlating with increased incidence of poor outcomes. The perception of increasing age resulting in increased risk is more likely associated with increased incidence of comorbid conditions. Simply put, healthy old people will have the same risks of surgery as healthy young people. This may be a good incentive for younger patients to maintain healthy lifestyles and physical fitness in anticipation of the increased likelihood that they may require surgery when they are older.

#### Risk from Anesthesia

Selection of type of anesthesia may also affect the overall risk of surgery, but the notion that local, regional, or spinal anesthesia is automatically safer than general anesthesia is not valid. The availability of a tracheal tube in a patient under general anesthesia allows optimal airway control and protection, which may offset the risks of such anesthesia in some patients. The use of "sedation analgesia," also known as *conscious sedation*, for some procedures allows the performance of certain procedures while the patient is still able to respond to commands and maintain his or her own airway (see Chapter 2, Procedural Sedation and Analgesia).

The selection of this technique, however, mandates strict adherence to monitoring and the availability of resuscitative equipment. Clinicians who use conscious sedation for procedures performed in office settings make considerable investments in training, equipment, and personnel in order to provide essentially the same level of care as is provided in a hospital setting.

For procedures performed in hospitals or ambulatory facilities that provide anesthesia team services, in the absence of compelling issues, it is usually best to leave selection of specific anesthetic modalities to the anesthesiologist. Specific concerns should of course be discussed with the surgeon and anesthesia team when indicated. It is helpful, however, for all clinicians to have an understanding of the risk classification system used by anesthesiologists (Box 230-1).

## PREOPERATIVE HISTORY AND PHYSICAL EXAMINATION

#### History

It has been noted that the history provides 90% of the information needed to tender good medical care, the physical examination provides 10%, and laboratory testing only confuses the matter. Although this may be a slight exaggeration, it is true that a careful and complete history is critical to good care and the ability of the consultant to provide appropriate recommendations.

The reasons for the planned procedure should be noted and should include the laterality of the affected organ or body part if appropriate. Events leading up to the procedure, especially those associated with trauma, should be reviewed for possible indicators of medical causes. For example, a fractured hip may be secondary to a fall, but the fall may be secondary to syncope related to intermittent complete heart block, which in turn may be secondary to Lyme disease

The past surgical history, including any reactions to anesthesia as well as family history of such reactions, must be noted and investigated, and any allergies to medications as well as sensitivity to latex must be prominently included in the report forwarded to the surgeon.

A complete *list of medications* being taken by the patient, including dose, route, and frequency, should include not only prescribed medications but vitamins, supplements, and herbal treatments. The common use of aspirin is an obvious concern, but other products such as nonsteroidal anti-inflammatory drugs (NSAIDs), omega-3 fatty acids, ginkgo biloba, or high-dose vitamin E can also affect bleeding. St. John's wort interacts with many medications.

## Box 230-1. Shortcuts to Determine Indicators for Noninvasive Testing before Noncardiac Surgery

No testing is necessary if the answer is "Yes" to any of the following four questions:

- 1. Is this low-risk surgery (e.g., endoscopic, superficial, cataract, breast, ambulatory surgery)?
- 2. Does the patient have fair functional/exercise capacity (≥4 METs) and no symptoms?
- 3. Has the patient undergone revascularization (coronary artery bypass grafting or percutaneous coronary intervention) within last 5 years without a change in symptoms indicating ischemia?
- 4. Has the patient had a thorough cardiac evaluation within last 2 years without a change in symptoms indicating ischemia?

Conversely, if vascular surgery is planned and the patient has three or more clinical risk factors (CAD, CHF, ASCVD, diabetes, or renal insufficiency), noninvasive testing is reasonable if the results will change the management.

Also, if the answer is "Yes" to both of the following two questions, noninvasive testing is reasonable:

- 1. Does the patient have poor functional/exercise capacity by questionnaire or specific questioning (<4 METs, or inability to climb one flight of stairs)?
- 2. Is a clinical risk factor present (CAD, CHF, ASCVD, diabetes, or renal insufficiency)?

ASCVD, arteriosclerotic cardiovascular disease; CAD, coronary artery disease; CHF, congestive heart failure; METs, metabolic equivalents.

From Fleisher LA, Beckman JA, Brown KA, et al: ACC/AHA 2007 Guidelines on perioperative cardiovascular evaluation and care for noncardiac surgery: Executive summary. A report of the American College of Cardiology/American Heart Association Task Force on Practice Guidelines (Writing Committee to Revise the 2002 Guidelines on Perioperative Cardiovascular Evaluation for Noncardiac Surgery). Circulation 116:1971–1996, 2007; originally published online September 27, 2007.

Aspirin, which irreversibly interferes with platelet function by inhibiting cyclooxygenase, has effects that last the entire 10-day lifespan of platelets, and must therefore be discontinued 10 to 14 days before surgery that has a risk for bleeding. The exception to this is for patients with known coronary or cardiovascular disease. Neither aspirin nor any other antiplatelet medications should be discontinued before dermatologic or dental procedures. Other NSAIDs such as ibuprofen also affect cyclooxygenase, but in a reversible fashion that lasts until the drug has effectively been cleared, usually after approximately five half-lives (10 hours for ibuprofen, which has an elimination half-life of 2 hours, but 3 days for naproxen, which has an elimination half-life of about 15 hours).

Patients should be questioned about history of angina, myocardial infarction, and symptoms suggestive of congestive heart failure such as dyspnea, orthopnea, or edema, as well as any recent cardiac testing such as stress tests or echocardiograms, the availability of which might obviate the need for repeat studies.

History of respiratory or cardiac conditions that might suggest the need for preoperative testing, or interventions such as bronchodilator treatments, should be noted and appropriate recommendations made. Factors such as obesity, likelihood of immobility, or altered coagulation and immunologic states should also prompt appropriate suggestions for both preoperative and postoperative care. Risk of postoperative deep venous thrombosis with secondary pulmonary embolism is increased by immobility and should prompt suggestions for prevention, which may include early ambulation if possible, use of sequential leg compression devices, or postoperative anticoagulation with heparin, enoxaparin, or warfarin. In some cases it may be prudent to discontinue medications that have prothrombotic properties, such as estrogen or oral contraceptives that contain estrogen.

Family history of deep venous thrombosis, early stroke, or other events that might suggest the possibility of an inherited tendency to hypercoagulability might prompt testing for such issues as factor V Leyden mutation, prothrombin mutation, or abnormalities of protein S or protein C, among others.

The history includes an assessment of functional cardiac capacity based on questions of tolerance of physical activity. The inability of the adult patient with more than minimal risk predictors to perform activity equaling at least 4 metabolic equivalents (METs) usually suggests the need for additional preoperative cardiac evaluation. Examples of activities that correspond to 4 METs include playing doubles tennis, climbing a flight of stairs, walking on level ground at 4 miles per hour, running a short distance, or doing moderately heavy housework such as scrubbing floors or moving heavy furniture.

For children, the history should include the birth history, any prenatal or perinatal complications, growth and developmental milestones, immunization status, and any recent illness, particularly respiratory infections.

The *last menstrual period* for women must be noted, as well as methods of birth control, menstrual history, and date of last Papanicolaou (Pap) test and mammogram. For patients with planned gynecologic surgery a pregnancy history should be taken, including types of delivery, obstetric anesthesia, and birth outcomes.

A history of nutritional deficiency for adults as well as children may have profound implications for wound healing and postoperative morbidity, and must be mentioned. It should prompt specific recommendations for preoperative nutritional evaluation and possibly the need for preoperative or postoperative nutritional support.

Smoking status must be reviewed and noted. Discontinuation of smoking 6 to 8 weeks before surgery is clearly beneficial in terms of reduced risk of cardiac and respiratory complications, as well as long-term health if the patient does not resume smoking. There is debate, however, about the effects of more proximate smoking cessation, especially if the patient discontinues cigarette use only a few days before surgery, which may lead to increased mucus mobilization as well as nicotine withdrawal symptoms. Alcohol consumption and nonmedical drug use are also important factors that should be considered in order to avoid unexpected withdrawal.

Elements of the patient's history will affect recommendations for antibiotic prophylaxis, including recent prosthetic joint surgery or other implanted devices, the need for endocarditis prophylaxis, or the need for other specific pharmacologic pretreatment such as stress doses of cortisone for dependent patients (e.g., patients with steroid-dependent asthma or Addison's disease).

#### **Physical Examination**

The physical examination starts with an accurate recording of the patient's vital signs, including temperature, pulse, respiratory rate, and blood pressure. Document height, weight, body mass index, and head circumference for children younger than 2 years of age. Orthostatic testing should be performed if there is risk or suspicion of hemodynamic compromise. The temptation simply to ask a patient his or her weight must be avoided, and only values and measurements actually obtained at the time of the consultation should be considered valid.

A full examination is performed with emphasis on the patient's known medical conditions and the type of surgery anticipated, remembering that the patient's care may not be ultimately limited

to the procedures, interventions, and types of anesthesia initially planned.

The report of the physical examination should mention pupil equality and reactivity, especially if the patient exhibits anisocoria (unequal pupils) at baseline. The condition of his or her dentition and the presence of braces, dentures, or other removable dental appliances should be noted, as should the absence of teeth, which should be identified by tooth number.

The presence of previously uninvestigated carotid bruits indicates the need for further work-up.

Recalling that the most serious surgical risk is associated with cardiovascular and pulmonary complications, careful attention should be paid to the examination of the heart and lungs, being alert for murmurs, gallops, wheezes, rales, crackles, or other signs of valvular disease, respiratory conditions, or congestive heart failure. The abdominal examination should include palpation for pulsatile abdominal findings that might prompt an assessment for aortic aneurism, and for renal bruits. The presence of ascites or a previously undocumented enlarged liver or spleen will prompt additional evaluation.

Assessment of extremity function, including motor strength, is important in patients undergoing joint surgery, but evaluation of peripheral vascular competency, including distal pulses and capillary refill, is essential in all patients because peripheral vascular disease is an important predictor of postoperative cardiac complications.

The neurologic examination should at minimum include a mental status evaluation that will serve as a baseline against which postoperative neurologic compromise will be measured. In some cases it may also be important in establishing the patient's ability to give informed consent.

As mentioned previously, the preoperative medical evaluation may be the patient's only opportunity for a complete medical assessment, and it may be appropriate to include an examination of the prostate, a breast and pelvic examination, or performance of a Pap test, even if they are not directly related to the planned procedure.

#### LABORATORY AND RADIOGRAPHIC TESTING

Preoperative laboratory testing should be based on the individual patient's underlying conditions, the potential for surgically related problems that relate to laboratory findings, or the potential that baseline or preoperative laboratory results might be helpful, should complications arise perioperatively. Most laboratory and diagnostic tests are *unnecessary* in healthy patients undergoing low- or intermediate-risk procedures, and in fact may lead to additional unnecessary testing if insignificant abnormalities are identified.

A baseline electrocardiogram should be obtained in patients with a history of diabetes, coronary artery disease, congestive heart failure, or poor functional capacity (<4 METs), or with evidence of peripheral vascular disease, cerebrovascular disease, or renal insufficiency. It is also probably reasonable in anyone undergoing vascular surgery.

Loss of physiologic variability in heart rate normally seen with respiration suggests possible autonomic dysfunction, which increases the risk of coronary artery disease in diabetic patients.

The patient with chest pain, new symptoms of congestive heart failure, or arrhythmias including ectopic beats should also be considered for noninvasive cardiac testing (e.g., exercise electrocardiography testing, nuclear stress testing, stress echocardiography). An echocardiogram with Doppler flow studies may also be helpful in assessing risk in patients with murmurs, physical findings suggestive of cardiomegaly, or symptoms that indicate decreased ventricular function. Results of recent testing may obviate the need for repeat studies if the patient's symptoms are chronic and unchanged in the past year or two.

The emergence of medications for treatment of erectile dysfunction has improved awareness of this condition as a marker for peripheral vascular disease and possible concomitant coronary artery disease. Patients taking these medications who have not previously been evaluated might benefit from preoperative noninvasive cardiac testing.

Hemoglobin should be measured in patients with history of anemia, bleeding disorders, diabetes, renal disease, hepatic disorders, human immunodeficiency virus infection, hypertension, or cardio-vascular disease, or with planned surgery in which significant blood loss is anticipated. The optimal hemoglobin level is related more to the patient's baseline and functional capacity than to a specific value. Although the traditional lower limit of 10 to 11 g/dL hemoglobin is a good approximation, the risks of transfusion must also be considered, especially in patients who normally function without difficulty at somewhat lower levels.

Preoperative supplementation of iron, vitamin C, and, when documented deficiency exists, folic acid or vitamin  $B_{12}$ , may help to optimize hemoglobin levels. The use of erythropoietin should be avoided in the absence of documented deficiency, usually related to renal or neoplastic disease. Serum creatinine and potassium should also be documented in such patients, along with serum glucose for patients with diabetes. Liver function tests (aspartate and alanine aminotransferases, gamma-glutamyltransferase, alkaline phosphatase, serum bilirubin) should be checked in patients with liver disease.

Use of diuretics or digoxin indicates the need for measuring potassium and magnesium serum levels as part of the preoperative evaluation.

On a practical basis, it is often simpler and frequently cost effective to obtain these tests as part of automated panels (complete blood count [CBC], basic metabolic panel, or comprehensive metabolic panel).

Patients on warfarin therapy will need to have the international normalized ratio (INR) checked before surgery, to ensure return to normal if treatment was stopped or to ensure therapeutic values if treatment is to continue uninterrupted. Patients at high risk of a cardiovascular event if warfarin therapy is discontinued should obtain "bridging" therapy with low-molecular-weight heparin or heparin.

A history or suspicion of cardiovascular or pulmonary disease will prompt the performance of a *preoperative chest radiograph*. They are otherwise generally not indicated unless related to the planned procedure, particularly if the patient has had a negative chest film in the past year.

Assessment of nutritional status can be very helpful in planning the need for nutritional support, especially in patients with signs of malnutrition. Measurement of *serum albumin below 3.2 gldL* or prealbumin below 15 mg/dL suggests the need for nutritional evaluation and possible supplementation before and after surgery. In some cases it may be prudent to postpone nonemergent surgery in nutritionally depleted individuals until this issue has been addressed.

Other preoperative laboratory evaluation should be specific to the patient's comorbid conditions or the specific nature and risks of the planned procedure. This may include a pregnancy test for women of childbearing age. Diabetic patients will benefit from urine protein screening and possibly measurement of creatinine clearance to assess for diabetic kidney disease.

## PATIENTS WITH CARDIAC AND PULMONARY DISEASE

Patients with past history of cardiac disease or at high risk of cardiac disease should be evaluated and managed preoperatively (Fig. 230-1). Such patients include those with recent myocardial infarction, unstable angina, significant valvular disease, hemodynamically significant dysrhythmias, or uncompensated heart failure, and those with poor functional capacity. Comorbid conditions such as pulmonary disease, diabetes (especially insulin requiring), kidney disease, and uncontrolled hypertension (diastolic blood pressure >100 mm

Hg) require careful consideration for preoperative evaluation and management.

#### **Cardiac Risk Factors**

Individuals with controlled angina, moderate symptoms of heart failure, or mild valve disease and those with borderline functional capacity should be considered for preoperative cardiac testing, especially if the planned procedure is high risk, because perioperative stresses may unmask or exacerbate previously controlled or compensated disease. Patients whose history and clinical presentation suggest the need for a cardiac evaluation independent of the planned surgery should have such evaluation regardless of their risk factors or the calculated risk of the specific procedure.

Patients who have had a recent coronary evaluation (within 2 years) or a revascularization procedure (within 5 years), and who are free of angina, ectopy, and clinical signs of heart failure, are at lower risk for perioperative complications, especially those with a fair exercise capacity (>4 METs). In the absence of such recent testing or interventions, the performance of preoperative testing for patients with significant cardiac risk factors should be considered. Exercise electrocardiography testing (see Chapter 93, Exercise Electrocardiography [Stress] Testing), stress echocardiography (see Chapter 94, Stress Echocardiography), or nuclear cardiac stress testing may be appropriate, and patients who are unable to perform treadmill testing should be evaluated with pharmacologic stress testing using dipyridamole, adenosine, dobutamine, or arbutamine. Table 230-1 provides shortcuts for determining whether a patient needs noninvasive testing. For intermediate- or high-risk surgery with only one or two clinical risk factors present, there is insufficient evidence to determine the best management, beta blockade therapy versus noninvasive testing.

Recent coronary stent placement (<10 weeks) presents specific issues related to the risk of early stent thrombosis. Long-term aspirin therapy for nearly all patients with coronary artery disease is supplemented with long-term clopidogrel in patients who have received coronary stents to prevent early stent occlusion until epithelialization has occurred. The use of drug-eluting stents has reduced the risk of early stent closure but presents the need for longer, perhaps lifelong antiplatelet therapy, with the risk of late stent thrombosis if such therapy is discontinued. Decisions regarding the risk of bleeding in a particular procedure weighed against the risk of stent closure must be made, as well as the timing of discontinuation and reinstitution of aspirin alone, or both aspirin and clopidogrel.

When considering the value of various cardiac tests as part of a preoperative medical consultation, the clinician must consider the individual patient's risk of progressive disease as well as the risk of the test itself compared with the risks of the surgery. Local expertise is also a consideration. The concerns of the patient, the anesthesiologist, and the surgeon who will be performing the procedure must be factored into the decision-making process. It is therefore important to maintain an open dialogue with patients, surgeons, and anesthesiologists to achieve trust and confidence among all involved.

#### **Anticoagulation**

Long-term anticoagulation with warfarin is common among patients with atrial fibrillation, artificial heart valves, history of recurrent thrombosis, and other conditions.

The safety of discontinuing warfarin before surgery depends on the underlying condition, and in some cases the patient may require heparin therapy while warfarin is discontinued, and again after surgery until a therapeutic INR is achieved. Such patients include those with mechanical heart valves or with a history of recurrent deep venous thrombosis associated with hypercoagulable states. The use of low-molecular-weight heparin such as enoxaparin on a short-term basis may be acceptable in some of these patients, but has been less studied than the use of intravenous heparin.

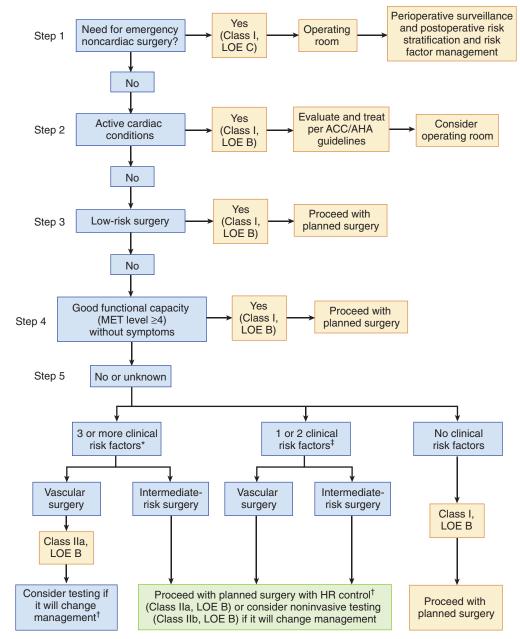

Figure 230-1 Cardiac evaluation and care algorithm for noncardiac surgery based on active clinical conditions, known cardiovascular disease, or cardiac risk factors for patients 50 years of age or older. \*Clinical risk factors include ischemic heart disease, compensated or prior heart failure, diabetes mellitus, renal insufficiency, and cerebrovascular disease. †Consider perioperative beta blockade for populations in which this has been shown to reduce cardiac morbidity/mortality. ACC/AHA, American College of Cardiology/American Heart Association; HR, heart rate; LOE, level of evidence; MET, metabolic equivalent. (From Fleisher LA, Beckman JA, Brown KA, et al: ACC/AHA 2007 Guidelines on perioperative cardiovascular evaluation and care for noncardiac surgery: Executive summary. A report of the American College of Cardiology/American Heart Association Task Force on Practice Guidelines [Writing Committee to Revise the 2002 Guidelines on Perioperative Cardiovascular Evaluation for Noncardiac Surgery]. Circulation 116:1971–1996, 2007; originally published online September 27, 2007.)

For patients taking warfarin because of atrial fibrillation or ischemic cerebrovascular disease (recurrent transient ischemic attacks), the drug can usually be discontinued 3 days before surgery and restarted at the usual dose on the first postoperative day if the surgeon deems the risk of postoperative bleeding to be low. This would allow the patient's INR to slowly return to normal around the time of surgery, and slowly return to a therapeutic level after surgery without leaving the patient fully untreated for more than 72 hours. Such a regimen is frequently used for outpatient dental procedures, although many dentists and oral surgeons will allow patients to con-

tinue warfarin therapy uninterrupted. Bridging therapy with low-molecular-weight heparin or heparin may be considered in patients with atrial fibrillation and at high risk for thromboembolism.

Patients with protein S or C deficiency, factor V Leyden mutation, or other inherited causes of hypercoagulability may require heparin therapy while warfarin treatment is restarted to avoid thrombosis if loading doses of warfarin are used.

Close communication with the operating clinician, surgeon, or dentist is important to avoid conflicting and confusing instructions to the patient.

<b>TABLE 230-1</b>	American Society of Anesthesiologists
Physical State	us Classification System

	•
Class	Description
1 2	A healthy patient with no significant medical problems A patient with mild systemic disease
3	A patient with severe systemic disease that is not incapacitating
4	A patient with severe systemic disease that is a constant threat to life
5	A moribund patient, not expected to live 24 hours regardless of treatment
6	A brain-dead patient who is an organ donor
Е	The "E" suffix is added to any class to indicate that the surgery is emergent.

#### Other Medications

Beta blockers should be continued in most patients already taking them, and initiation of such treatment before surgery should be considered in patients with high cardiac risk (ischemia on preoperative testing) who are scheduled for vascular surgery and other procedures that present increased risk of cardiac stress. These patients may be at high risk of perioperative cardiac events and expert consultation may be of benefit in determining appropriate therapy. Several authors have suggested withholding angiotensin-converting enzyme inhibitors and angiotensin receptor blockers the day of surgery and only restarting them postoperatively after euvolemia has been established in order to decrease the risk of perioperative renal dysfunction. A meta-analysis of 11 studies with 1007 patients (Mukherjee and Eagle, 2003) suggested that calcium channel blockers significantly reduced ischemia and risk of supraventricular tachyarrhythmias and were associated with trends toward reduced perioperative death and myocardial infarction.  $\alpha_2$ -Adrenergic agonists have been shown to reduce mortality and myocardial infarction in patients undergoing vascular surgery. More specifically, clonidine has been studied prospectively and found to cause minimal hemodynamic effects and reduce postoperative mortality for up to 2 years.

Statins, widely used for long-term control of serum cholesterol, are also known to have beneficial effects in stabilizing atherosclerotic plaques. Their use preoperatively in patients with known coronary artery and ischemic cerebrovascular disease should be considered.

#### **Pulmonary Disease**

Preoperative evaluation of patients with pulmonary disease, including asthma, emphysema, or conditions that may affect oxygen diffusion such as lupus or sarcoidosis, may benefit from pulmonary function testing and baseline measurement of oxygen saturation as well as diffusing capacity. Optimization of therapy with inhaled beta agonists, inhaled steroids, and oral steroids may help reduce postoperative complications such as atelectasis, pneumonia, and exacerbations of obstruction. Intravenous stress doses of steroids (e.g., hydrocortisone sodium succinate [Solu-Cortef] 100 mg) might also be considered in patients who are steroid dependent. This may need to be balanced against considerations of steroid effects on wound healing and fluid balance. A preoperative nebulizer treatment with albuterol or another beta-active medication is often helpful. Patients with increased risk of postoperative atelectasis, including those with planned thoracic or abdominal surgery, may also benefit from preoperative teaching in the use of an incentive spirometer.

Sleep apnea, most common in adult men, should be noted in previously diagnosed individuals and considered in patients with typical body habitus (obese, short neck) and history of snoring, fatigue, and observed apneic episodes while sleeping. Sleep studies may be appropriate and the use of postoperative continuous positive airway pressure (CPAP) might be considered.

#### **PATIENTS WITH DIABETES**

Control of blood glucose levels, as well as recognition of conditions that frequently are associated with diabetes, are important concerns in the preoperative evaluation of diabetic patients. If sufficient time is available before surgery, an attempt should be made to bring the patient under good glycemic control through adjustment in their usual oral medications or insulin dosages, or initiation of insulin therapy if necessary. Attempting to maintain normal blood sugars postoperatively, especially after major surgeries, has been proven beneficial for diabetic patients. In addition, undiagnosed patients at risk for metabolic disease, including diabetes, would benefit from screening before surgery.

The stress response to surgery can result in hyperglycemia, and this should be considered in the planning of diabetic therapy. Perioperative dehydration may also result in elevated blood glucose, ketosis, and potential acidosis, especially in patients with type 1 diabetes

Non-insulin-requiring patients with diabetes with planned minor surgical procedures, who are expected to be able to resume normal diets soon after surgery, may be able to continue their oral medications up to the morning of surgery. Patients with type 2 diabetes who are scheduled for such procedures, and who will be NPO for more than 4 to 6 hours, may be instructed to discontinue short-acting insulin on the evening before surgery and take half their usual intermediate- or long-acting insulin dose on the morning of surgery.

Patients taking glargine (Lantus) may be instructed to take half of their usual dose the evening before surgery and to discontinue oral medication at that time. Normal insulin and oral regimens may be resumed when the patient returns to a normal diet.

Longer procedures that entail more extensive periods of NPO status require a more detailed approach to preoperative glycemic control. This may include discontinuation of oral medications 48 to 72 hours before surgery and institution of intermediate-acting insulin (NPH, Novolin) with preprandial blood glucose measurements and sliding scale administration of short-acting insulin (Humalog, Regular, NovoLog). Type 1 and some type 2 insulinrequiring diabetic patients may require continuous insulin infusion preoperatively along with a separate intravenous glucose infusion. The use of subcutaneous doses of short-acting insulin may yield unpredictable responses in patients with altered peripheral perfusion, and these patients may also benefit from continuous intravenous insulin infusion that can be monitored and adjusted with greater accuracy. Careful attention to fluid balance and serum electrolytes, especially potassium, is also critical to avoiding complications.

Patients with diabetes are at risk for silent ischemia as well as ventricular dysfunction and may benefit from preoperative cardiac evaluation if not recently performed. Renal status should also be confirmed, understanding that a normal preoperative serum creatinine level, although somewhat comforting, may not reflect the patient's reserve capacity and response to surgical stress.

Communication with the surgeon, anesthesia team, and postoperative nursing staff is important in the management of diabetic patients, and may best be done directly rather than through written means if concerns about the patient's perioperative management exist. The trend toward ambulatory surgery and early discharge also requires careful instructions to the patient about postoperative management and may warrant specific preadmission teaching.

#### **PATIENTS WITH LIVER OR KIDNEY DISEASE**

#### Liver Disease

The presence of known liver disease, including cirrhosis, hepatitis, or obstructive biliary disease, may predispose patients to nutritional deficiency as well as coagulation disorders. Preoperative evaluation should include studies to identify such disorders, including serum

albumin or prealbumin, clotting time, prothrombin time (INR), and CBC to assess hemoglobin and platelets. Some patients may require perioperative administration of fresh frozen plasma or other blood products, supplementation of vitamin K to correct elevated INR, or specific clotting factors. Platelet infusions have very brief benefit and should be used only if counts are critically low. Most patients with platelet counts above 60,000 do not exhibit abnormal bleeding on the basis of thrombocytopenia.

Antibiotics that are cleared through the liver should be avoided or dosages adjusted appropriately, and sedatives with hepatic metabolism must be used with caution. Amide anesthetics (lidocaine, bupivacaine, mepivacaine) commonly used for local and regional anesthesia are cleared through the liver and must be used with caution in patients with known liver disease, as well as elderly patients whose hepatic function may be naturally reduced.

#### **Kidney Disease**

Patients with kidney disease may have stable mild chronic renal insufficiency, which, if their reserve is minimal, may progress to acute renal failure perioperatively.

Others may already be on dialysis, and others may be categorized as somewhere between these two extremes.

Chronic renal disease predisposes patients to anemia, platelet dysfunction, metabolic acidosis, hyperkalemia, and uremia. They also have higher incidences of peripheral vascular disease, coronary artery disease, and ischemic cerebrovascular disease. Preoperative evaluation therefore must identify individuals at risk of electrolyte imbalance and fluid status abnormalities and increased risk of worsening renal impairment, as well as of cardiac and respiratory disease.

Preoperative testing should include measurement of serum electrolytes, bicarbonate, creatinine, blood urea nitrogen, calcium, CBC with platelet count, coagulation studies (prothrombin time/INR, bleeding time), urinalysis, and arterial blood gas if bicarbonate is decreased (<16 to 18 mEq/L). The electrocardiogram and chest radiograph should be reviewed and repeated if not recent. Unless the patient is undergoing dialysis, results of recent measurement of renal function, including creatinine clearance, should be reviewed.

Timing of dialysis in enrolled patients should be discussed with the nephrology or dialysis team, and is usually performed on the day before surgery to optimize fluid status and reduce uremic bleeding complications. Serum potassium levels should be checked within 3 to 6 hours before surgery and corrected to less than 5 to 5.5 mEq/L using bicarbonate/dextrose/insulin infusion, unless the patient has responded well to previous use of binding resins. Anemia as low as 7 to 8 g/dL hemoglobin may be well tolerated in patients with chronic renal failure; however, if functional capacity, coronary ischemia, respiratory compromise, or likelihood of significant surgical blood loss are a concern, the patient may benefit from judicious transfusion of packed red cells. If time permits, erythropoietin therapy may be considered.

#### **BARIATRIC SURGERY**

The growth of the availability and variety of surgical procedures aimed at treating obesity has offered hope for many patients who have struggled with weight loss. In many cases these procedures offer life-changing remedies, and the results of surgery are often encouraging to patients, their families, and their clinicians. In many cases, however, the results are transient because behaviors and extrinsic factors return the patient to an obese state, now with an altered alimentary tract. The true nature and helpfulness of bariatric surgery will require ongoing research, and the perioperative risks remain underestimated and poorly understood.

The immediate concern for many primary care clinicians whose patients undergo evaluation for bariatric surgery is the preoperative surgical protocol followed by many, if not most, bariatric surgeons.

This protocol mandates a standard list of subspecialty consultations, usually including cardiology, pulmonary, endocrinology, gastroenterology, and frequently psychiatry, in addition to dietary and nutritional counseling. The patient is also usually told to see his or her primary care clinician, for "clearance."

The question in the mind of the primary care clinician may then be, what additional service or advice can he or she offer that has not already been offered by the myriad of medical professionals already consulted? Or, what is the motivation of the surgeon in asking for a "clearance" from the patient's primary care clinician, when the decision has apparently already been made that expertise beyond the scope of the primary care clinician is required?

Although many primary care clinicians enthusiastically advocate for the role of "patient manager," others see this situation as a result of proactive medicolegal defensiveness on the part of the surgeon. These primary care clinicians understand the risks, both known and unknown, of these particular planned procedures, and understand the perception of the surgeon about how many consultations should be on the patient's chart and of what variety.

It has consequently become the usual and customary practice of many primary care clinicians to withhold an opinion as to the fitness of their patients for bariatric surgery, to limit their consultative reports to an accounting of the patient's medical history, including that of their obesity and attempts at weight loss, and to leave recommendations about preoperative optimization to the other specialists involved.

#### **PREGNANT PATIENTS**

Nonobstetric surgery may be required during the course of nearly 2% of otherwise normal pregnancies. Appendectomy, cholecystectomy, orthopedic procedures after trauma, or other emergent procedures must not be delayed because of concurrent pregnancy. Surgery that is nonobstetric but related to pregnancy, such as urologic interventions or ovarian surgery, may also be required. In these cases, the axiom that a pregnant patient is treated in the same fashion as a nonpregnant patient applies. The safety and well-being of the fetus depend in the greatest degree on the health of the mother.

When possible, elective surgical procedures should be performed during the second trimester, when organogenesis is less affected and the risk of preterm labor is decreased. Advanced pregnancy may affect diaphragmatic excursion and predispose the patient to atelectasis and postoperative risk of pneumonia; therefore, pulmonary function should be evaluated and the use of incentive spirometry considered. Antibiotic selection should avoid drugs with known fetal adversities, such as tetracycline in early pregnancy or NSAIDs pear term.

Preoperative medical evaluation of the pregnant patient centers on the same considerations of operative and anesthesia risk, patient risk factors, and the need for perioperative care as with a nonpregnant patient.

#### **COMMUNICATING RECOMMENDATIONS**

The results and report of the preoperative consultation should be forwarded to the requesting surgeon (or dentist, clinician) promptly. Inpatient consultations will be posted to the patient's chart and reviewed by the surgeon and anesthesia team. Although local protocols may request that reports of outpatient medical evaluations be sent directly to the hospital or ambulatory surgical center, it is the responsibility of the consultant (the primary care provider in this case) to ensure that findings and recommendations are in fact received by the surgeon. For this reason, many clinicians forward the preoperative evaluation to the surgeon and directly communicate the need for him or her to provide the results to the hospital or other surgical facility. The establishment of good communication and relationships helps to guarantee effective information sharing for the benefit of the patient.

Many formats, forms, and designs for both printed and electronic transmittal of preoperative medical evaluations are available, but the standard dictated letter that includes the patient history, physical examination, laboratory, and diagnostic findings and recommendations may be most useful and, as noted at the beginning of this chapter, may constitute the only comprehensive document containing this information in the patient's chart. It should include a statement of the patient's condition relative to his or her fitness for the planned procedure, indicating that no "current medical contraindications" exist, or, if they do exist, what specific steps need to be taken to reduce the risks compared with the urgency of the surgery.

#### **CPT/BILLING CODES**

99241–99245 Office consultations 99251–99255 Inpatient consultations

**NOTE:** Determining the level of complexity for consultations is similar to determining use for other office- and hospital-based evaluation and management (E&M) services.

#### **ICD-9-CM DIAGNOSTIC CODES**

- V72.81 Preoperative cardiovascular examination
- V72.82 Preoperative respiratory examination
- V72.84 Preoperative examination, unspecified

**NOTE:** V72.84 can be used in addition to the specific diagnosis code for the underlying condition.

# PRINCIPLES OF X-RAY INTERPRETATION

Wm. MacMillan Rodney • J.R. MacMillan Rodney • K.M.R. Arnold

#### INTRODUCTION

Studies on imaging outcomes have documented quality of care for interpretation of radiographs by nonradiologists in family medicine and emergency medicine. This chapter provides a "how-to-do-it" guideline on the interpretation of the most common adult x-ray studies needed in primary care: common fractures of the long bones and the chest radiograph (posteroanterior and lateral). (For the treatment of fractures and further discussion, see Chapter 190, Fracture Care.) There will also be an overview of the purchase, maintenance, and staffing of equipment in the office. This includes the decision to have all or selected images interpreted by outside consultation. Published data suggest that consultation significantly changes management in less than 2% of cases if the physician has basic interpretation skills.

#### Who Reads the Film and Who Collects the Fee?

Practicing medicine in today's world entails medicolegal risk. It cannot be eliminated, but it can be lessened by timely application of procedural skills such as interpretation of radiologic images at the point of service. The advantages of bedside correlation and subsequent follow-up cannot be overemphasized.

Primary care residency training is adequate to train clinicians to interpret images or to seek consultation when needed. Levels of comfort vary from physician to physician. There is no legal requirement to have images interpreted by a radiologist. Physicians are entitled to reimbursement for the technical component (TC) and the professional component of the CPT-4 charges for the image if they own the equipment, and create the formal report for the medical record. Only the physician signing the final report is entitled to bill for the professional component of the fee.

#### **Buying the Equipment**

Digital radiography offers lower-cost and more reliable technology in the office. From a storage perspective, the space that developers, darkrooms, and films (both exposed and unexposed) occupy can be more efficiently used for patient care. Digital technology also promotes safety by eliminating developer chemicals that must be stored and disposed. Also, by decreasing the number of retakes, radiation to patients and office staff is reduced. Finally, images are easily stored and can be shared more quickly and efficiently, which prevents unnecessary repeated studies and minimizes expense and radiation exposure.

Computed radiography (CR) is less expensive and equally accurate as the picture archiving and communication systems purchased by hospitals. CR refers to the use of phosphor films that function in the cassettes of traditional x-ray equipment. The image is taken; the plate is transferred to a developer; and then the image is loaded

digitally to the computer. Installation of a new digital CR system costs less than \$60,000. Digital images can be inserted directly into most electronic medical record systems.

## State Certification, Licensing Laws, and Insurances Vary

A lead-lined room is necessary to obtain state certification. This can be done for less than \$10,000. Physicians do not require additional licensing to provide radiographs, but unlicensed staff must usually take a 6- to 10-day course and pass a state test for licensing. Hiring a dedicated radiology technician is an expensive option that may be beyond the budget of an office taking fewer than 25 images a day. Data suggest that offices order 3 to 8 radiographs per 100 patients per day. Geriatric and urgent care—open access practices have higher demand

Planning and cost—benefit analyses must be completed before the purchase of equipment and staff training (see Appendix L: Buying Major Office Equipment). Some HMO contracts forbid reimbursement to office-based physicians, but some emergency departments are charging over \$200 per chest film. An average Medicaid reimbursement may be less than \$40 per image. Local reimbursement rates, insurance rules, governmental policies, and patient mix must be reviewed before purchasing an x-ray unit.

#### **CHEST RADIOGRAPHY**

One example of documentation that helps ensure that all aspects of the radiograph are reviewed is shown in Figure 231-1. This documentation form helps maintain quality of care. Obtaining a second opinion (over-reading by a second physician) is suggested until the reader becomes comfortable with the many variations of normal versus abnormal.

## Interpretation Guidelines for the Adult Posteroanterior and Lateral Chest Radiograph

#### Clinical Context

The clinician who performs the history and bedside examination has a tremendous advantage compared with a radiologist remote in time and space. The immediacy of clinical data differentiates imaging as a diagnostic procedure for the patient in real time versus a radiologic consultation, which usually occurs after the patient has left the office. The bedside examination at the point of service minimizes errors of interpretation.

#### Validity

Images must be labeled and dated and there must be a system in place to ensure this is done.

- 1 <del>0</del> a	se fill this form out completely.  CLINICAL CONTEXT

Figure 231-1 Interpretation of the chest x-ray report form.

Posteroanterior (PA) and lateral views are the standard views for the cooperative adult. "PA" simply means the beam travels in the direction from the back to the chest (vs. "AP" [anteroposterior], from chest to back). The patient stands and takes a deep breath. Views are standardized as noted later. Cardiomegaly definitions are different on PA versus AP views, so it is important that radiographs be taken appropriately. Without a lateral view, lesions in the retrocardiac and poststernal (anterior clear space) space can be missed. Other potential views are not covered here.

"Perfect views" are not necessary to gain useful information, but a disclaimer describing any technique limitations must be inserted with every film. For chest films, the acronym *RIP* describes the characteristics of *rotation*, *inspiration*, *and penetration* (i.e., exposure). These validity checks must be addressed before any interpretation of findings.

#### **POSTEROANTERIOR VIEW**

 Is this film rotated? In the PA film, measure the distance from the spinous processes of the vertebral bodies to the medial heads of each of the clavicles. These are easily identifiable bony landmarks. Commonly, there is a 2- to 3-mm difference because of slight rotation, which does not invalidate the film, but in general,

- the distances on the right and the left should be approximately the same.
- Is there an adequate inspiration? Inadequate inspiration is a cause of decreased specificity (increased opacity) for lung parenchyma. The "best" method for measuring inspiration is by counting posterior ribs as they join the spine. A minimally adequate inspiration uncovers nine ribs. Avoid counting anterior ribs, which are less predictable.
- Is the amount of penetration within normal limits? Penetration describes the amount of radiation exposure applied to the tissue. A practical rule of thumb for evaluating overpenetration and underpenetration is the anatomic point at which the vertebral interspaces are no longer visible. An overpenetrated PA chest image will create a "spine film" with all elements of the vertebral bodies visible down into the abdomen. An underpenetrated film will be too "white." When penetration technique is ideal, intervertebral spaces disappear somewhere in the cardiac shadow and do not appear beneath the diaphragm.

Overexposure "burns out" the ability to see the lung parenchyma and vessels, that is, turns the lung fields black. The vessels normally start to disappear as they approach within 3 to 4 mm of the chest

wall. Overexposure increases the probability of false-negative interpretation.

Physicians should comment on limitations of interpretation caused by suboptimal technique. The physician should request additional views or insert a disclaimer about technique if necessary. This includes the need for a lateral image in the ambulatory adult and older child.

These validity checks, and the following system for reviewing the film, establish guidelines for quality assurance.

#### Check the Lateral Image

Review the spine, diaphragms, anterior clear space, and the retrocardiac space. The majority of diagnoses will come from the PA view.

## Does a Survey of the Bones and Soft Tissues Reveal Any Significant Abnormalities?

This area is of limited value when the radiograph has been ordered to investigate dyspnea, cough, hypertension, and other routine cardiovascular issues. However, a systematic sweep of the bones and soft tissues is mandatory.

## Is the Appearance of the Mediastinum within Normal Limits?

The physician cannot miss a shifted or widened mediastinum, which is associated with aortic dissections, pericardial tamponade, tumors of the thymus and thyroid, lymphoma, and germ cell teratomas. A quoted dimension for "wide" is 8 cm in the average adult. Another method measures the mediastinal width at the level of the carina. If it is more than 25% of the thoracic diameter, it is considered "wide." A "thin" mediastinum has no significance. However, aortic dissections have occurred in mediastina measuring less than 8 cm. Normal children younger than 5 years of age frequently have a "wide" mediastinum and large cardiac silhouette.

## Does a Review of the Cardiac Silhouette Reveal Any Significant Abnormalities on the Posteroanterior View?

Cardiomegaly exists if the transverse diameter of the heart on a PA view is greater than 50% of the transthoracic diameter measured at the same level. The thoracic diameter is measured from one side of the rib cage to the other at the level of the middle of the heart. An enlarged pulmonary artery segment can be seen as an extra hump on the left side of the PA heart. On the lateral, left ventricular enlargement can cause a shadow more than 2 cm posterior to the shadow of the inferior vena cava. Pneumopericardium creates a black line around the border of the heart. The thin heart of deep inspiration, such as in chronic obstructive pulmonary disease, is not indicative of cardiac disease.

## Does a Review of the Diaphragms Reveal Any Significant Abnormalities (Posteroanterior View)?

Air beneath the diaphragms is a surgical emergency until proven otherwise (it documents a bowel perforation). Normally the right diaphragm is higher than the left by 2 to 20 mm. Abnormal elevation occurs from lung atelectasis, paralysis, effusion, lobectomy, and other causes.

#### Lungs

Now the lung tissue itself is evaluated.

- 1. Are there any significant abnormalities on the left or right hilum? In 70% of normal patients, the left hilum is higher than the right, and at equal elevations in 30%. The right hilum in not normally higher than the left. Abnormal hilar adenopathy indicates serious infection, sarcoid, or malignancy in most cases.
- 2. Are there any significant abnormalities to the lung parenchyma? A rapid visual "ping-pong" comparison of the left and right lung fields should detect flagrant asymmetries caused by pathologic processes such as hemothorax, metastatic nodules, sarcoid, primary tuberculosis, and pneumonias. Failure to detect an obvious abnormality in the face of a seriously ill patient may require consultation or hospitalization.

Poor inspirations and AP views cause false-positive "fluffiness" similar to congestive heart failure (CHF) patterns. Normally on the PA film, the vascular markings stop short of the lung wall by 3 to 5 mm. Gravity causes subtle tapering of the vessels as they go toward the head (cephalad). "Cephalization of flow" is jargon for the phenomenon of enlarged lung vessels in the upper lung fields secondary to CHF.

The *silhouette sign* helps the clinician to localize the lesion. In the chest, there are anatomic structures that exist in fixed air–soft tissue relationships. Given proper rotation and penetration, the heart borders, the ascending and descending aorta, the aortic knob, and the diaphragms are visible (Figs. 231-2 and 231-3). The silhouette sign describes the situation where parenchymal pathology masks the silhouette of a common anatomic landmark. The heart and diaphragm are most commonly affected. For example, when anterior left upper lobe pneumonia obscures the border of the left heart, it is called a silhouette sign. When pleural effusion obscures the contour of the diaphragm, it is a silhouette sign.

Nodules are classified by their diameter of 5 to 30 mm. Above 30 mm, these lesions are classified as masses. Small lesions (2 to 10 mm) are common. Most of these are calcified granulomas, and vessels on end. They are small and innocent, and do not grow over time. They can be followed by serial radiographs and clinical history. Positron emission tomography scans can differentiate

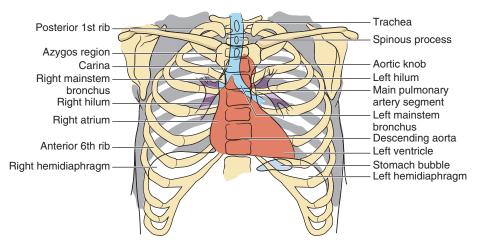

Figure 231-2 Schematic anatomy of posteroanterior chest images.

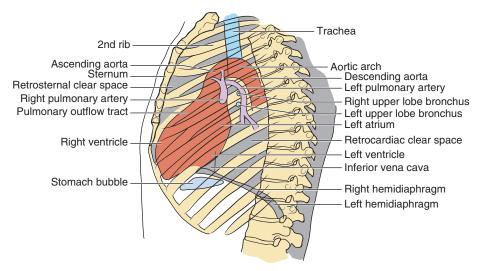

Figure 231-3 Landmarks of the lateral chest film.

metabolically active lesions (malignant, infectious) from those that are metabolically quiescent (benign).

3. Are there any significant abnormalities of the lung pleurae? The absence of pulmonary vasculature extending out to the bony inner edge of the thorax indicates a pneumothorax until proven otherwise. The visceral pleura is the outer lining of the lung, and the parietal pleura is the inner lining of the chest cavity up against the bones and muscles. The area between the two, the pleural space, under normal conditions, is a potential space. Pleural effusions are caused by primary disease processes such as infection, neoplasm, and inflammation. Specific diseases such as subphrenic abscess, hepatitis, and pancreatitis can cause effusions. Cardiac failure, renal failure, or any disease that alters the osmolar and hydrostatic equilibrium among the body compartments can cause effusions. Untreated chronic pleural effusions can cause loculations and adhesions.

#### Interpretation

- 1. Within normal limits.
- 2. Normal, but I want to comment on some findings which are probably insignificant. Consultation not required, but ... (perhaps the penetration was not ideal or the entire right shoulder was not seen, etc.).
- 3. Questionable findings exist and consultation will be requested. This could include a computed tomography scan of the chest, which is the most commonly ordered test for ambiguous findings on the plain radiograph. Consultation reports can be ambiguous or wrong. CHF can appear to be pneumonia, and vice versa.
- 4. Abnormalities include the following: Naming the disease is not necessary. Stating that the entire right lung is "whited out," or that "multiple 2- to 3-cm nodules are present in both lungs," will lead to dramatic changes in management that will be mentioned in the plan.

#### Plan

By offering an interpretation or a "preliminary interpretation" in the office at the point of service, quality is improved. Clearly indicate in the report any intention of further diagnostic studies or follow-up, which can then be immediately explained to the patient. Poorly worded or ambiguous interpretations that arrive hours or days after the patient has left the office decrease the quality of care.

Consultant reports can be lost or misplaced. The beauty of imaging in the office is the high predictive value of a positive finding. Specificity is high when lesions are obvious, and delay of management pending formal interpretation is often not wise. The risk of a false-negative result (low sensitivity) is always present.

Multiple studies have documented, however, that the rate of failure to diagnose a lesion of significance is less than 1% to 2%.

#### Top 10 "Normal" Tips

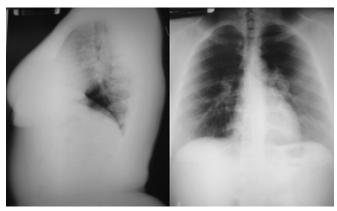

- 1. You are at the bedside. Integrate the history with the physical findings and be sure they correlate.
- The clavicular heads are equidistant from the spinous processes.
- There are at least nine ribs visible on a normal inspiratory PA view.
- 4. The intervertebral spaces should not be visible beneath the diaphragm.
- 5. Before 5 years of age, a normal thymus can make a large-appearing mediastinum.
- 6. In adults, the mediastinum should not measure more than 8 cm.
- 7. The left hilum is higher than the right hilum.
- 8. The right diaphragm is higher than the left.
- 9. The exact boundary distinguishing a granuloma from a nodule may not be as important as the clinical context, which includes a history for risk and the rate of growth. Lesions greater than 10 mm in diameter may benefit from a second opinion.
- There is no exact formula for hilar enlargement and subtle parenchymal change. Chance favors the prepared mind. Read or perish.

#### Sample Chest Radiograph Presentations

Make copies of the report form (see Fig. 231-1) and fill it out for each of the following images. Check your findings against the information given in the figure legends.

Figure 231-4: This is a 43-year-old African-American woman with a 3-month history of increasing fatigue and shortness of breath. Other than being overweight, her past medical history is noncontributory. Her lungs were clear to auscultation and vital signs were normal.

Figure 231-5: A 59-year-old white man with a long history of chronic obstructive pulmonary disease reports a mild cough, a mild increase in dyspnea, and a fever last night. He has dropped out from care in the cardiology and pulmonary clinics. Many years ago he was told he needed a heart operation, but he has refused. He is demanding an antibiotic shot because his "pneumonias" start like this. His lungs are clear and his heart sounds are distant. His vital signs are normal, including a respiratory rate of 16 per minute.

**Figure 231-4** On the posteroanterior (PA) film (right), there is clinically insignificant rotation with an adequate inspiratory effort. The left costophrenic angle is partially cut off. Penetration (exposure) is somewhat strong but not clinically significant. The bones are normal, but soft tissue breast shadows are causing transparent opacity over the lower outer lung fields bilaterally. The mediastinum and cardiac shape are normal. The right hemidiaphragm is slightly higher than the left, and the left hilum is slightly higher than the right. Both hilar areas are enlarged and there is paratracheal node enlargement on the right in the area of the clavicle. There are parenchymal streaks extending down and outward from the hilar areas, but they do not constitute infiltrates.

Although the lateral film (*left*) does not record an optimal inspiration, it does not change the findings on the PA film. Taken together, the films are adequate for an interpretation of "abnormal chest." Rather than repeating the films, the patient was sent for computed tomography of the chest. The differential diagnosis includes sarcoidosis, lymphoma, and tuberculosis, among others. This was biopsy-proven sarcoidosis.

Figure 231-6: This patient complains of acute chest pain radiating to the back. A 33-year-old Latino man with an unremarkable past medical history walked away from a motor vehicle accident last night. He reports that he was hit in the chest very hard. He is in moderate distress, with a pulse of 110 beats per minute and blood pressure of 100/70.

Figure 231-5 The initial impression is overexposure with blackening of the lung fields, but the vertebral interspaces are not obvious. Clearly, there is an adequate inspiration without rotation. Bones and soft tissues are unremarkable, but the mediastinal and cardiac contours look abnormal. The diaphragms are flattened, as is common with patients with chronic obstructive pulmonary disease, suggesting a hyperaeration common with these patients. The opacities on the right do not constitute a mass or an infiltrate of significance. The lateral view (right) reveals flattened diaphragms and a barrel chest. This accentuates the anterior clear space in front of the heart and the retrocardiac space, which do not contain any abnormal findings. The extra hump on the left side of the heart is significant enlargement of the pulmonary artery segment, and it is likely that the patient has a compensated congenital heart defect.

**Figure 231-6** The mediastinum is widened, and the diagnosis is traumatic aortic dissection. Overall, the film is insignificantly rotated with an adequate inspiration. Nine posterior ribs are showing, but the film is mildly underpenetrated—underexposed. Minor imperfections in technique are the rule, not the exception. The mediastinal findings are sufficient to send the patient to the hospital.

The bones and soft tissues are inconsequential. The left hilum is higher than the right, and the right hemidiaphragm is higher than the left. The underexposure makes the parenchymal markings more prominent, but they do not represent infiltrates. As with all previous images, there is no air under the diaphragms.

Figure 231-7: A 23-year-old Latina woman presents with cough and fevers for 1 month. Past medical history is noncontributory. Figure 231-8: A 68-year-old white woman with a history of uncontrolled hypertension and dyspnea, worsening today. Vital signs are pulse 105, blood pressure 190/115, temperature 98° F, and respiratory rate 24 per minute. She is in mild distress.

**Figure 231-7** Example of infiltrate on right, calcified hilar node on left, visible sequestration in minor fissure on left—and more. Lateral image did not add to the information seen here. The diagnosis is tuberculosis.

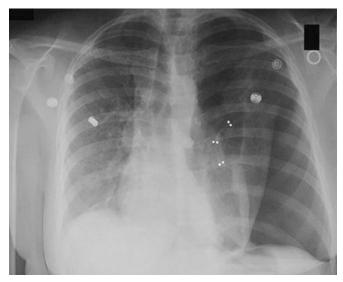

**Figure 231-8** Good example of cardiomegaly and "cephalization" of flow. Inspiration is adequate, with nine visible posterior ribs. The heart measures greater than 50% of the transthoracic distance. Blood vessels at a level superior to the tracheal bifurcation appear larger than those at the level of the midheart. This is the reverse of what would normally be seen. Cephalization is another term for the "reversal of flow" seen in congestive heart failure. This is a good view demonstrating the clavicular heads as equidistant from the spinous processes of the spinal column. In this case, the lateral image did not change the management.

Figure 231-9: A 55-year-old smoker coughed up blood this morning and presents with cough, fever, and purulent sputum. Lateral view does not change management.

Figure 231-10: This patient is a 27-year-old man with reported gunshot wounds to chest and pneumothorax. The patient is unable to stand and is tachycardic and clammy. The image was obtained using portable technique, AP view.

**Figure 231-9** Bilateral acute pneumonia. Note abnormalities of cardiac border on the left and right. This is a good example of the silhouette sign with the right heart border obscured by an inflammatory process. This man was sent for computed tomography, which led to tissue diagnosis of lung cancer.

**Figure 231-10** Because the patient is unable to raise his arms, the scapulae are in the lung fields, but interpretation of the most significant event is reasonable. There is a bullet in the right side and buckshot in the left. The heart is shifted to the right and the radiograph confirms the need for chest tube insertion. The entire left lung is collapsed. Note the absence of vascular markings on the left. Although a lateral image would localize the depth of the bullet and buckshot, the emphasis should be on stabilizing these critical injuries.

#### LONG BONE FRACTURE RADIOGRAPHS

#### Tips for Reading Long Bone Fractures

- Study the terminology of fractures as given in Chapter 190, Fracture Care, and in a reprint of Musculoskeletal Medicnel Office Orthopedics by Wm. Rodney, MD (available online at www.psot.com [see under rural family medicine, predoctoral section, ortho 101, assigned reading]).
- Use comparison images of the injured with the noninjured bone in children with growth plates.
- Study the Salter system for fractures in children. Prognosis worsens as the Salter number increases. Salter 1 and 2 fractures can be managed conservatively.
- When any radiographic image is indicated, take the time to view each one in detail, looking at the bones too. This is what develops one's sense of "normal."

Finding fractures is guided by the location of the point tenderness. The clinician then requests two or three views to determine stability features such as displacement, angulation, and involvement of a joint. Positioning is an art, not a science. Make sure that you follow the cortex (edge of the bone) for any breaks in the line. These small defects are fractures, especially when they are associated with point tenderness.

Fracture detection is made more difficult by technique that is overpenetrated (too black). Nondigital films may be clarified by the use of a hot lamp technique in which the film is placed directly over a bright light. Digital films can be electronically corrected in several ways. Underpenetrated films (too white) may lead to false-negative findings. Without digital software, these images need to be retaken. Digital manipulations can correct some of the underpenetration errors in technique.

There are specific soft tissue clues that increase the probability of a fracture even when one is not immediately visible. The best known is the *fat pad sign* associated with occult fractures of the bones surrounding the elbow. This sign is defined by a hypolucent (i.e., dark) space immediately adjacent to the injured bone. It usually represents blood released by the acute injury. A *posterior fat pad sign* is clearly abnormal, whereas an anterior fat pad may normally be visible for 1 to 2 mm. Larger than that is abnormal.

Primary bone tumors are rare, but appear as hyperopaque (osteo-blastic) or hypo-opaque (osteoclastic) lesions, with occasional detection by the spontaneous occurrence of pathologic fractures. Metastatic bone cancers, for example, from the prostate or breast, are more common. Fractures may be the first sign of an undiagnosed malignancy.

Those taking and reading their own radiographs should be reasured by the fact that most orthopedists depend on their own interpretations. The opportunity for clinical correlation is a tremendous help in achieving optimal management for the patient. The importance of examining the cortex with specific attention to the area of point tenderness cannot be overemphasized. Digital films allow magnification for subtle lesions. In the extremities, particularly in children, comparison views of the noninjured limb may lead to a more accurate diagnosis.

#### **General Guidelines for Fracture Care**

See Chapter 190, Fracture Care, for more detail.

• Even after the bones heal, many fractures have minor, but residual discomfort and possible minor changes in function for up to 1 year later. Physical therapy will not remove this.

- Open (compound) fractures require immediate antibiotics.
- Stability governs prognosis as well as the possible need for consultation.
- Fractures that are nondisplaced, nonangulated, transverse/oblique, and without involvement of the joint space are more stable.
- Fractures that are comminuted, spiral, and involving the joint space are less stable.
- Review the patient context and factor in comorbidity. For example, fractures in the elderly heal more slowly and are at higher risk of sustained discomfort. Patients with mental illness or sociopathic behavior require additional care.
- If providing care for a fracture, see the patient on days 2, 7, and 14 postinjury. If the pain is not resolving, consultation should be considered.
- Healing times and follow-up protocols vary. For nonoperative fractures, young people heal more rapidly than seniors.

#### **Common Fractures**

Make copies of the report form (Fig. 231-11) and fill it out for each of the following images. Check your findings against the information given in the figure legends.

Figure 231-11 X-rays for sports, trauma, and workplace injuries report form.

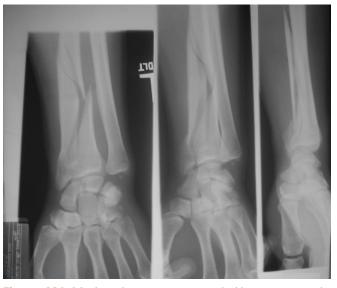

**Figure 231-12** A "bump" is visible on the radius proximal to normal epiphyses (growth plates). This is a torus fracture where the cortex of the bone has buckled. Although classified as a fracture, there is no displacement, angulation, joint involvement, or visible fracture line. Conservative management with simple protective devices will lead to a good result.

Figure 231-12: A 10-year-old girl fell on her arm 2 hours ago while playing outside. There is point tenderness over the left distal radius, but otherwise she has no significant physical findings. Figure 231-13: A 19-year-old man "broke his arm 3 months ago and the cast was removed 4 weeks ago." He fell again today and wants to know if he refractured the forearm.

**Figure 231-13** Lateral views demonstrating normal callus formation with no evidence of a new fracture. Patient and family can be reassured. No additional casting is necessary.

**Figure 231-14** Lateral, posteroanterior, and oblique views are the recommended views. Physicians should consider characteristics that affect fracture management. In this fracture, the joint space is involved and this is associated with instability and a higher risk of subsequent arthritic pain. Instead of being transverse or oblique, this fracture has a spiral nature, but it is not distinctly comminuted (i.e., more than two pieces). It is a classic example of a complicated fracture destined for orthopedic surgery.

Figure 231-14: A 27-year-old man fell on his arm yesterday, and he could not sleep last night. The arm is swollen and extremely painful to the touch. His neurovascular examination is negative, but there is limited range of motion secondary to pain.

Figure 231-15: A 10-year-old boy experienced a collision on the soccer field this afternoon. He continued to play briefly, but states that he does not wish to move his arm.

Figure 231-16: A 23-year-old man tripped playing touch football. He was unable to walk.

**Figure 231-15** The focal point of this image is the shoulder and its growth plate, which is normal. However, there is a nondisplaced, nonangulated fracture of the clavicle. We treated this with a sling and range-of-motion exercises three times a day.

**Figure 231-16** Lateral (*left*) and oblique (*right*) views reveal a fracture of the distal fibula, which is simple, oblique, nonangulated, and nondisplaced, and does not involve an articular surface. It was immobilized with a cast for 6 weeks. No orthopedic consult was obtained.

Figure 231-17: A 38-year-old jogger hit a pothole and inverted his ankle. There was an audible "pop," and exquisite pain was immediate. The neurovascular examination is negative.

Figure 231-18: A 79-year-old farmer was brought by his daughter, who insisted that he be evaluated after a fall from a dumpster the preceding day. He is ambulating with a walker, and insisting that he "only needs a tetanus shot."

Figure 231-19: A 23-year-old basketball fan hit the wall with his fist yesterday. The pain is great and he would like an evaluation. His

**Figure 231-18** This is a nonangulated but seriously displaced fracture of the proximal femur. It is probably intertrochanteric and transverse. It is not comminuted, but a request for surgical consultation should be noted in the medical record. The patient refused surgery and left with his walker. He died of pneumonia 9 months later (at home).

**Figure 231-17** This is a noncomminuted, nonangulated, nondisplaced, oblique fracture of the distal third of the fibula. There is no involvement of an articular surface. There is a spiral component to the fracture on the posteroanterior view (*left*). Worse yet, there is displacement of the tibia on the talus. Note the abnormally large distance from the medial malleolus to the talus. This indicates separation of the interosseous membrane. This is a highly unstable fracture that received orthopedic surgery.

**Figure 231-19** In contrast to "compound" fractures, simple fractures are those in which the skin is unbroken and the bone is not "sticking out." This was the case here. There is a fracture at the distal fifth metacarpal bone, but it does not involve the articular surface of the joint. There is 45 degrees of angulation, but no displacement. This is the classic "Boxer's fracture." Attempts at reduction are unlikely to affect the end result, which is good function and minor cosmetic deformity.

**Figure 231-20** A cast has been placed on the hand after a reduction maneuver. The radiograph has been taken with the cast on. It is tempting to deduce that the bone fragments are in better alignment, but at least two views would be necessary to make this judgment. Complete immobilization would require encasing the entire hand in concrete. This is not possible, and these fractures almost always return to their original position.

neurovascular examination is negative, but pain limits his ability to flex and extend the fourth and fifth digits.

Figure 231-20: What has happened to the preceding case?

Figure 231-21: A 14-year-old boy's hand was stepped on during his first football game. It is painful and swollen, but the worst pain occurs in the area of the third metacarpophalangeal joint. Is there a fracture?

Figure 231-22: A 17-year-old female basketball player was trying to perform a dunk and landed on her outstretched hand with imme-

**Figure 231-21** A Canadian family physician, Robert Salter, created the Salter classification of pediatric fractures. This is a Salter 3 fracture with a fracture on the ulnar side of the epiphysis of the proximal third digit. It involves the joint space, but the size of the fracture is so small that it was treated conservatively.

**Figure 231-22** This is a simple, noncomminuted, nondisplaced, nonangulated fracture of the scaphoid bone. A thumb spica cast should be applied for 6 to 8 weeks, and the patient should be warned about the possibility of nonunion.

diate pain, but little swelling. Neurovascular examination is negative, but there is a loss of range in motion at the wrist secondary to pain. Pain localizes to the area between the first metacarpal and distal radius.

## SPECIAL CONSIDERATIONS IN GERIATRIC PATIENTS

Gerald A. Amundsen • Kalyanakrishnan Ramakrishnan • Robert Salinas

Patients in the geriatric age group often have multiple chronic illnesses associated with functional decline of major organ systems. In addition, there are normal physiologic changes associated with aging that are universal to all. These diseases and changes, along with the medications used to treat them, may complicate outcomes of office procedures and influence physician decisions regarding timing, technique, aftercare, and whether or not to perform the procedure at all.

Currently, people 65 years of age and older account for approximately 12% of the U.S. population, a number expected to approach 20% by the year 2030. This group consumes approximately one third of health care provided, and a higher percentage of office surgical procedures. The physician performing office procedures must understand the underlying physiologic changes associated with aging and approach them with caution to achieve the common goals of diagnostic accuracy and relief from symptoms, while maintaining functional independence, and improving quality of life.

The subclinical losses in organ function with advancing age, although rarely the cause of substantial illness or disability, impede optimal recovery and increase susceptibility to complications (Table 232-1).

#### INFLUENCE OF COMORBIDITIES

The elderly are more likely to have poorly controlled chronic diseases such as coronary artery disease, diabetes mellitus, hypertension, peripheral vascular disease, or chronic obstructive pulmonary disease. In the absence of significant functional reserves, exposure to sustained physiologic stress may result in acute decompensation and organ failure.

Heart disease affects over half the population 65 years of age and older. Orthopnea associated with congestive heart failure (CHF) influences patient positioning, frequently dictating the need to avoid Trendelenburg and flat supine positions, which may cause dyspnea. Electrolyte imbalance caused by diuretics may induce arrhythmias during procedures. Valvular heart lesions may dictate the need for endocarditis prophylaxis. In the presence of coronary artery disease, sublingual nitroglycerin should be available during surgery, and perioperative use of epinephrine should be minimized or avoided.

Hypertension is associated with perioperative bleeding and cardiovascular complications, as well as postoperative hematoma formation. Achieving normotension before even minor, elective surgery minimizes bleeding. Hypertensive responses to pain, hypoxia, hypercarbia, and hypothermia during surgery may be avoided through judicious use of analgesics, respiratory support, and maintaining ambient room temperature. Procedures may be performed while taking precautions to minimize stimuli elevating blood pressure and ensuring perioperative cardiovascular stability.

Patients with *diabetes mellitus* have defects in immune function, vasculopathy, and neuropathy, which increase risk for infection and poor healing. Efforts should be made to tighten blood sugar control before any significant procedure. Prophylactic antibiotics should be a strong consideration.

Hypoxemia and hypercapnia associated with *chronic obstructive pulmonary disease* can be associated with respiratory decompensation as well as right-sided CHF, tissue edema, and impaired mental status. These patients may also be steroid dependent. Hypoxia, coexisting CHF, and steroid use delay wound healing. Once again, consider antibiotic prophylaxis for any surgical procedure. Oxygen, nebulized bronchodilators, and positioning options should be available for potential respiratory decompensation.

Peripheral vascular disease is chronic, progressive, and debilitating and adversely affects the patient's ability to perform daily activities. Ischemia and tissue hypoxemia associated with peripheral vascular disease delays wound healing. Postoperative infection may precipitate gangrene in areas already affected by critical ischemia. Prophylactic antibiotics may help prevent this.

Bleeding diathesis due to anticoagulants or diseases such as myeloproliferative disorders may result in intraoperative bleeding and postoperative hematomas. These risks should be detected and corrected to minimize surgical complications.

Stroke victims more commonly have associated cardiac arrhythmias or coronary artery disease, so extra precaution needs to be taken in this population. In addition, commonly used antiplatelet agents or anticoagulants place this group at higher risk for wound hematoma and subsequent infection. Neurologic deficits may hinder recovery and postoperative care and may also present difficulties in obtaining informed consent.

Hypothyroidism may have protean manifestations (e.g., musculoskeletal or mobility disorders, depression and dementia, slowing of speech and thought processes, cerebellar dysfunction, neuropathy, and macrocytic anemia with or without pernicious anemia). Patients with mild to severe hypothyroidism may also have exaggerated responses to local anesthetics.

Neuropsychiatric manifestations of vitamin  $B_{12}$  deficiency may include fatigue, weakness, memory loss, and depression. Peripheral or sensory neuropathy may result in urinary or fecal incontinence, ataxia, spasticity, and abnormal gait. Hematologic features include pancytopenia and hepatic dysfunction. These manifestations may influence the informed consent process, as well as anesthetic and surgical techniques.

Hyperviscosity syndrome due to multiple myeloma, other plasma cell dyscrasias, leukemias, or polycythemia is generally not diagnosed until the seventh decade of life. Associated fatigue, weakness, skin and mucosal bleeding, and neurologic manifestations such as paresthesias and ataxia impede healing. Features of the illness and treatment measures (antimitotic agents and plasmapheresis) delay

<b>TABLE 232-I</b>	Senescent Changes with Aging
Organ	Changes and Effect
Skin	<ul> <li>Loss of subcutaneous fat, thinning of epidermis and dermis</li> <li>Decreased sensory perception</li> <li>Decrease in collagen, mast cells, fibroblasts, vascularity</li> <li>Greater susceptibility to injury, delay in wound healing, slowed reepithelization</li> </ul>

	Effect on drug distribution, binding

LV, left ventricle.

wound healing, increase risk of infection, and influence the impact of any procedure.

Pedal edema not only can make lower extremity surgery more difficult, it increases the likelihood of slow healing and infection. Whether the edema is from CHF, venous insufficiency, or other causes, any surgical intervention on the area should be accompanied by leg elevation, prophylactic antibiotics, and delayed removal of sutures.

Approximately 10% of elderly patients have some form of *cognitive impairment*, increasing to 47% among those institutionalized. Cognitive impairment may limit ability to give informed consent, follow instructions regarding aftercare, or comply with medication requirements. These patients are not excluded from office procedures, but there is an increased need to assess the level of functional independence and address the potential need to involve a surrogate caregiver.

#### **PREOPERATIVE ASSESSMENT**

It may be best to schedule the assessment weeks before the procedure so that a focused history, examination, and relevant tests can be carried out. This also allows for optimizing treatment of comorbidities, identification of barriers to obtaining informed consent, and mobilization of support systems. Most elderly patients depend on numerous family and social systems to maintain their independence, and these caregivers should be informed as to the treatment plan and details of postoperative care. Modifications to medications, antibiotic prophylaxis, and bowel preparation should also be addressed at the initial visit. In patients with multiple comorbidities, it may be beneficial to consult with other physician colleagues to minimize risks and optimize outcomes.

The approach to the patient must be geriatric oriented. In addition to the history and physical, elements of functional assessment should be evaluated. The extent of assessment should be determined by the level and potential impact of the procedure on the patient. Psychosocial assessment should address cognitive, affective, functional, environmental, and economic issues.

Most, if not all, office procedures are "low risk" and there is insufficient evidence either to advocate routinely performing any given test on the basis of age or to clearly define preoperative tests that are of value. Morbidity after office procedures is not affected by commonly ordered preoperative tests, so laboratory tests should be ordered only when the history or an examination finding indicates a need. A chest radiograph and electrocardiogram do not reduce adverse postoperative outcomes and are not usually required.

#### **Medication Issues**

A detailed list of medications, including those available over-the-counter (OTC) and herbal preparations, is important in assessing risks associated with office procedures. Medications can influence perioperative and postoperative outcomes by their effect on wound healing and hemostasis, and through drug interactions. Classes of drugs affecting surgery include antiplatelet agents, anticoagulants, corticosteroids, nicotine, antineoplastic drugs, antihypertensives, antidepressants, and herbal medications. Most older Americans (80%) take at least one prescription medication and three OTC drugs every day, and there is a linear relationship between the number of drugs taken and the potential for complications. Although it usually is unnecessary to alter or withhold medications, the risks and benefits of discontinuing medications must be carefully weighed with particular emphasis on potential complications, always with the goal of minimizing complications.

Aspirin, antiplatelet agents, selective serotonin reuptake inhibitors, and nonsteroidal anti-inflammatory drugs (NSAIDs) may cause perioperative bleeding by inhibiting platelet aggregation. Traditionally, aspirin has been discontinued for 2 weeks and most NSAIDs 2 days before elective surgery. Nonaspirin, non-NSAID pain relievers are recommended postoperatively. Warfarin, a potent inhibitor of vitamin K-dependent factors, also increases bleeding risk. Recent publications have encouraged continuing both NSAIDs and other anticoagulants during cutaneous surgical procedures by demonstrating that complications are not reduced by their brief perioperative discontinuation. If it is necessary to stop oral anticoagulant therapy before performing the office procedure, warfarin can be replaced with bridge therapy using low-molecular-weight heparin (enoxaparin). Warfarin is usually stopped 5 days before the procedure and recommenced the day after. Enoxaparin is dosed at 1 mg/kg every 12 hours or 1.5 mg/kg daily in the interim. Both the low-molecularweight heparin and warfarin are given for 2 to 3 days after the procedure to ensure anticoagulation while the warfarin takes effect. With any of these agents, meticulous hemostasis during office procedures must be ensured.

Unwanted *drug interactions* are typically avoidable with careful preoperative assessment. *Electrolyte levels* should be monitored if indicated based on comorbid illness or medication use, and imbalances corrected before surgery. The use of epinephrine in the presence of hypokalemia can induce cardiac arrhythmia. *Propranolol*, when used with epinephrine, has been known to cause malignant hypertension and reflex bradycardia. However, rebound hypertension and worsening angina may follow abrupt discontinuation of

<sup>\*</sup>Serum creatinine is not an accurate reflection of creatinine clearance in the elderly.

TABLE 232-2 Medications Interfering with Wound Healing		
Agent	Mechanism	
Aspirin, ticlopidine, dipyridamole, clopidogrel (Plavix) Corticosteroids	Wound hematoma     Disturbance of fibrin matrix     Decrease fibroblast and epidermal proliferation, formation of granulation tissue, protein and collagen production     Decreased inflammatory response     Increase wound infection rates     Vasoconstriction	
Antineoplastic agents	Decreases immune response to infection, increased infection rates     Interference with cell division	
Colchicine, penicillamine, phenytoin	Interference with cellular turnover	

propranolol or other beta blockers. Abrupt withdrawal of benzodiazepines and antipsychotics may lead to significant hypertension and mental status changes; their use should therefore be continued. Monoamine oxidase inhibitors may interact with epinephrine, phenylephrine, and meperidine, leading to serotonin syndrome (hypertensive crises, mental status changes, fever, muscle cramps, seizures, and coma). Tricyclic antidepressants or selective serotonin reuptake inhibitors administered for chronic depression need not be discontinued before surgery because this may worsen anxiety, agitation, and depressed mood. It has been suggested that tricyclic antidepressants be stopped 1 to 2 weeks before surgery if use of epinephrine is anticipated, because of the potential arrhythmogenic effect; with the minimal doses used in the office setting, however, this is rarely, if ever, a significant factor. Potential complications of herbal supplements include coronary ischemia, stroke, bleeding, and interactions with anesthetic agents. Vitamin E, ginkgo biloba, ginseng, and garlic all inhibit platelet aggregation and increase risk of bleeding and hematoma.

Several agents commonly used in the elderly population delay wound healing (Table 232-2).

#### **Assistive Devices**

Many older patients may have eyeglasses, hearing aids, and dentures that are essential to their independence, nutrition, and social interaction. Other assistive devices to be considered include *pacemakers*, *prosthetic joints or extremities*, *and assistive mobility devices such as wheelchairs*, *canes*, *and walkers*. Procedures should be modified to minimize intraoperative problems associated with these devices and minimally affect their postoperative use. In *pacemaker-dependent patients*, electrosurgery near the heart or pacemaker site should be avoided. If such surgery is contemplated, the indifferent (ground) electrode is placed far away from the pacemaker site and short bursts of current lasting less than 5 seconds should be used. The cutting currents have a higher likelihood of interfering with the pacer.

#### **Competence and Informed Consent**

Physical competence specifically refers to the patient's physical ability to participate in the preoperative, intraoperative, and post-operative phases of office procedures. Mental capacity, on the other hand, is defined as the patient's ability to understand the nature and risk of the procedure, along with postoperative care instructions. The elements required to give informed consent include the ability to understand and remember treatment options, risks, and benefits, and the capacity to make decisions consistent with personal values and goals. Sensory and cognitive impairment are associated with impaired understanding and difficulties in communication. Several

effective methods have been used to improve understanding in these patients before obtaining consent, including simplified instructions, videos, instructions printed in large font, and use of health educators, patient quizzes, and multiple office visits to alleviate potential confusion. These strategies should be considered in designing materials, forms, policies, and procedures for obtaining informed consent. When the patient is deemed unable to fully understand the information and instructions, the next-of-kin or a legally appointed caregiver should participate in the process.

#### **ANTIBIOTIC PROPHYLAXIS**

See Chapter 221, Antibiotic Prophylaxis, and Chapter 222, Prevention and Treatment of Wound Infections.

The goals of prophylactic antibiotics are (1) to prevent wound infection and (2) to avoid endocarditis. Antibiotics to prevent wound infection are probably indicated even in clean wounds in the oral cavity, axilla, and perineum, or when there are minor breaks in aseptic technique, where the infection rate is less than 10%. Contaminated wounds (post-traumatic wounds, major breaks in sterile technique, wounds compounded by inflammation) have a 20% to 30% risk of infection and require antibiotics for 3 to 7 days. Wounds grossly contaminated with foreign bodies or with devitalized tissue have a 30% to 40% risk of infection and require more prolonged antibiotic treatment (7 to 14 days). There are no reliable studies confirming the effectiveness of this approach and the optimal duration of antibiotics in these classes of wounds.

In addition, for the office practice, wound prophylaxis should be strongly considered in the very old, those with suspected poor nutrition, those who are immunosuppressed for any reason or have diabetes, and for large wounds and for surgery on the lower extremities in the presence of edema or peripheral vascular disease.

Topical antibiotics facilitate wound healing by keeping the wound moist, increasing the removal of debris, and reducing the surface bacterial count. They may both promote and retard the rate of reepithelialization of wounds, and may also cause allergic reactions. Sterile petrolatum is an inexpensive and effective alternative that is less likely to cause an allergic dermatitis or promote bacterial resistance. Although "moist healing" is the standard in the elderly, the moist environment may lead to maceration and skin breakdown. After the first few days, wounds may do better being left open to "dry" for a good portion of the day.

A significant proportion of reported cases of infective endocarditis have no known predisposing source, and most cases are not due to invasive procedures. Although antibiotic prophylaxis against endocarditis had been recommended in the past for dermatologic procedures in patients with valvular heart disease and prosthetic valves, more recent recommendations by the American Heart Association have not mandated this because of the low risk of endocarditis after these procedures. Office procedures associated with development of endocarditis include oral hygiene and dental procedures, especially in the presence of gum disease, nasal cautery for epistaxis, fiberoptic endoscopy of the gastrointestinal tract, barium enema, and genitourinary procedures such as urethral catheterization. Patients at high risk of development of endocarditis include those with cardiac prosthetic valves and those with previous episodes of endocarditis. Indwelling pacemakers pose a low risk of development of endocarditis. Most evaluations have also found routine prophylaxis for patients with prosthetic joints unnecessary.

#### **AFTERCARE AND FOLLOW-UP**

In the absence of any significant physical or cognitive limitations, most patients recover well after office procedures. Patients should be encouraged to resume activities of daily living as early as possible. Medication changes should be reviewed carefully. Written and verbal postprocedure instructions for wound care, pharmacotherapy, and follow-up should be given to the patient or caregiver.

If significant pain is anticipated after the procedure, analgesics should be continued, making allowances for temporary functional limitations they may impose. If narcotic analgesics are used, they should be accompanied by a gentle bowel stimulant such as senna to prevent constipation and fecal impaction. Symptoms suggesting complications (e.g., wound infection, sepsis, deep venous thrombosis if immobilization is anticipated, bleeding and bowel perforation after endoscopy) should be explained to both patient and caregiver to maximize opportunities for early intervention. In cognitively impaired or homebound patients, a home health care agency or skilled nursing services may be useful in assisting with postprocedure monitoring and ensuring optimal recovery.

#### **CONCLUSION**

The turn of the century has brought with it a large group of older people in need of health care and support. When contemplating office procedures, it is mandatory that physicians familiarize themselves with the additional demands that aging, illness, polypharmacy, and the presence of assistive devices place on these patients.

## **BODY PIERCING**

Peter Valenzuela

Modification of the body in the form of piercing and skin art has been demonstrated in virtually every culture dating back to at least 2000 BC. Egyptian pharaohs pierced their navels, and Roman soldiers pierced their nipples. Perhaps better known are the piercings and body art of African and Native American communities. In the United States, female ear piercing has long been accepted, but in the last 25 years male ear piercing and the piercing of other body areas have become widespread. Today, navel piercing is one of the most fashionable piercings. More extreme piercings of the eyebrows, nipples, lips, tongue, and genitals have also become common. With this in mind, primary care physicians may decide to offer body piercing to their patients.

Physicians have the advantage of being trained in anatomy, physiology, and aseptic technique, which are vital to performing safe piercings. In addition, physicians can recognize potential complications and have the capacity to therapeutically intervene early and effectively. Even if physicians choose not to perform body piercing, they need to be familiar with the techniques and complications that are unique to body piercing.

#### **ANATOMY**

Commonly pierced areas of the body include the ears, eyebrows, tongue, nose (i.e., ala, septum, and bridge), umbilicus, nipples, lips, and genitals. Each site carries unique risks. The physician needs to be cognizant of these risks when evaluating whether to pierce a specific location, and needs to counsel the patient accordingly.

#### **INDICATIONS**

- Cosmetic procedure
- No traditional medical indications
- The clitoral hood piercing may improve the sexual experience for women who have lost sensitivity

#### **CONTRAINDICATIONS**

- Skin and systemic disorders: Medical contraindications to body piercing are related to external factors involving the skin and to systemic conditions. Local skin infection, a cyst, severe eczema, or any other significant skin disorder at the site is a contraindication to piercing. A history of keloid formation, not necessarily hypertrophic scarring, is also a condition that warns against piercing.
- Steroid use and coagulation disorders: Chronic steroid use or a coagulation disorder also precludes the procedure.
- Immunodeficiency syndromes: Patients with an immunodeficiency disorder, such as acquired immunodeficiency syndrome (AIDS), present unique difficulties. For many of these patients, body modification is an important part of life, and the piercing would benefit their overall sense of well-being. Although, theoretically, AIDS might be considered a contraindication to piercing, realistically, unless the patient's T-cell levels are significantly compromised,

- piercing can be successfully accomplished in the patient with AIDS.
- Pregnancy: Clinicians should discuss pregnancy intentions with women seeking nipple or navel piercings because healing can take 2 to 4 months. Controversy exists regarding whether a nipple piercing affects lactation. There are 15 to 20 milk ducts in the nipple. Although scar tissue may occlude some ducts, a properly placed piercing with appropriate jewelry should not adversely affect breast function. Excessive scarring may lead to duct occlusion, which could cause decreased or absent milk expression, persistent breast engorgement, and increased risk of infection or abscess formation during lactation. Women interested in nipple piercings should be aware of the unknown and potentially adverse effects on the ability to breast-feed. Also, because the infant may aspirate the jewelry or develop metal allergies, the jewelry is removed during actual breast-feeding.

Navel piercings can take 6 to 10 months to heal. This should also be taken into consideration if a pregnancy is being considered. Navel piercings also tend to migrate. Tissue distortion that occurs during pregnancy can exacerbate this problem, and it may be necessary to remove the jewelry as gestation progresses.

#### **EQUIPMENT**

#### Jewelry

It is important to use the proper jewelry to avoid complications. Patients should wear only jewelry made of surgical-grade stainless steel (316 L [low carbon], 316 LVM [low carbon, volume melt]), titanium, niobium, platinum, solid white or yellow gold (14K or 18K), or Tygon. Gold-plated jewelry contains reactive metals such as nickel and can cause allergic reactions. Silver will tarnish in the moist environment of a new piercing or in contact with any mucosal surface.

The most common types of jewelry are bead ring, captive bead ring, straight barbell, circular barbell, and curved barbell (Fig. 233-1). Size is defined in terms of gauge and either diameter or length. If the jewelry is not provided by the physician's office, patients should be advised to purchase the jewelry that is appropriate for the piercing they desire and bring it with them. Table 233-1 summarizes the initial jewelry commonly used for each location.

The bead ring and captive bead ring are opened and closed either by hand or with specialized ring-opening, ring-closing pliers. The use of other pliers may distort the shape of the ring. It is important to maintain the integrity and shape when opening and closing the ring.

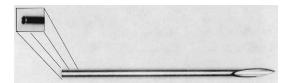

#### **Piercing Equipment**

- Appropriate jewelry: sterilize in an autoclave.
- Antiseptic cleanser: use povidone-iodine (Betadine), Techni-Care, or ethyl alcohol.

Figure 233-I Jewelry styles: straight barbell (top), captive ring (left), circular barbell (center), curved barbell (right), and labret stud (bottom).

- Ring-closing pliers: use with captive or bead rings; usually not needed if jewelry is annealed. (The annealing process allows jewelry to be manipulated more easily, particularly by hand.)
- Piercing needles: have various sizes available, including 10, 12, 14, 16, and 18 gauge. (For most piercings, the needle size should match the gauge of the jewelry being inserted [Fig. 233-2].)
- Needle-receiving tube: use for piercings involving the nostril, septum, penis, clitoral hood, and some parts of the ear cartilage (Fig. 233-3).
- Rubber bands: use to provide tension for piercing clamps.
- Insertion taper: a solid metal rod that is larger at one end and
  gradually becomes smaller at the other end; gauge measurement
  is based on size of larger end; use to help transfer jewelry or for
  stretching; in a fresh piercing the taper's gauge will be the same
  as the jewelry gauge. Transfer means to place the tip of the jewelry
  into the needle or taper and pass it into place in the hole previously made by the needle.
- Needle pusher/acrylic needle holder: helps pass the needle through skin.
- Tissue forceps: use Pennington, mini-Pennington, or ring forceps; slotted style is optional. (The forceps is tensioned with two rubber bands; this helps avoid clamping skin too tightly.)
- Surgical marking pen: use very fine point. (Sharpie Fine Point pens can be used.)
- Gentian violet: to mark tongue and oral cavity piercings.
- Toothpicks: to apply gentian violet.
- Cotton applicators: use to adjust the size or site of insertion marks at the piercing site; erase or fine-tune the marks with alcoholsoaked applicators.

**Figure 233-2** Piercing needle. This is a hollow, tribeveled needle. Jewelry is held against the nonpointed end of the needle for passage through the skin. After passage, a cork can be placed on the needle tip to prevent needlestick injuries.

- Gauze: to cleanse the site after piercing.
- Gauge wheel: confirm gauge of needle or jewelry.
- Caliper: confirm size of jewelry.
- Sterile barrier field: cover instrument tray.
- Cork: cover needle tip after insertion. (Protects against needle injury.)
- Ethyl alcohol (70%): can use as a skin cleanser. (Removes excess ink marks.)

#### **Sterilization**

Most piercing equipment can be sterilized in an autoclave (270° F under high-pressure steam for at least 10 minutes). Items that are reusable should be cleansed in an ultrasonic cleaner before sterilization. Those items that are heat sensitive can be cleansed with a broad-spectrum, environmentally safe germicidal that kills such organisms as human immunodeficiency virus (HIV), hepatitis (particularly B), and tuberculosis. When possible, piercing guns should be avoided because most cannot be properly sterilized. Those patients choosing to have a body piercing done at a piercing salon should be advised to search for members of the Association of Professional Piercers. In addition, the piercer should possess certifications for basic life support/cardiopulmonary resuscitation and blood-borne pathogens training.

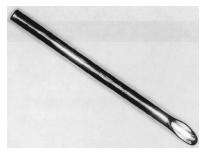

## PREPROCEDURE PATIENT EDUCATION AND FORMS

Inform the patient of all possible complications of piercing in general and those specific to the location requested. Thorough documentation of the informed consent is mandatory. All patients younger than 18 years of age need legal guardian consent. Patients should anticipate the average healing time depending on the loca-

TABLE 233-I Jewelry Selection			
Location	Type and Size	Gauges*	Comments
Ear lobe Ear cartilage (outer) Ear cartilage (tragus) Eyebrow Nostril Nasal septum Tongue	BR, CBR, or LB; ¾-½ inch BR, CBR, or LB; ¾-½ inch BR, CBR, or BB; ¾-¾ inch BR, CBR, BB, or LB; ¾-½ inch Nostril screw; BR, CBR; ¾-½ inch BR, CBR, BB or CB; ¾-½ inch BB; ¾-I inch	18–10 gauge 18–14 gauge 18 or 16 gauge 18 or 16 gauge 20 gauge; 18 gauge 16–10 gauge 14–10 gauge	Avoid ear studs; occlusive and difficult to clean Choose jewelry least likely to be uncomfortable during sleep Choose jewelry least likely to be uncomfortable during sleep Risk of tearing with smaller gauges; risk of migration with larger gauges Nostril screw has small loop at right angle to hold it in place Use a needle-receiving tube Length accounts for initial edema; downsize jewelry in 2–3 weeks; minimum ball size is 6 mm
Labret Nipple (female)	Labret stud; $\frac{3}{8} - \frac{1}{2}$ inch BR, CBR, BB, or CB; $\frac{8}{8} - \frac{3}{4}$ inch	14 gauge 14–10 gauge	Minimum ball size is 5 mm; can downsize later Consider future breast-feeding plans; postpone piercing if pregnancy is
Nipple (male) Navel Clitoral hood (vertical) Penis (Prince Albert)	BR, CBR, BB, or CB; %6 inch BR, CBR, or LB; %6-% inch BR, CBR, or LB; %6-%6 inch BR, CBR, LB, or CB; %6-1 inch	14 or 12 gauge 14 or 12 gauge 14 or 12 gauge 14 or 12 gauge 12 or 10 gauge	in the near future  Pierce navel fold; avoid small jewelry that can constrict skin  Position jewelry so that ball rests on the clitoris  Use a needle-receiving tube

BB, straight barbell; BR, bead ring; CB, circular barbell; CBR, captive bead ring; LB, curved barbell.

<sup>\*</sup>When using gauge readings, the size actually decreases as the gauge number gets larger.

**Figure 233-3** Needle-receiving tube. This is a hollow tube that is used in ear cartilage, nostril, and genital piercings. The needle is passed through the area being pierced into the tube. The tube protects adjacent structures from inadvertent injury.

tion of the piercing (Table 233-2). (See the sample patient education and consent forms online at www.expertconsult.com.)

#### **TECHNIQUE**

Universal precautions should always be followed. Instruments and jewelry need to be appropriately sterilized. In rare circumstances, certain jewelry will need to be soaked in an antiseptic solution for 30 minutes. This solution is removed with alcohol before insertion. Anesthesia is usually not indicated for these procedures. However, for sensitive areas such as the genitals and mucosa, topical anesthetics like topical lidocaine (EMLA cream) or benzocaine (Hurricaine) can be applied before the procedures.

#### **Navel Piercing**

- 1. Prepare the sterile instrument tray (Fig. 233-4).
- Clean the navel and the surrounding abdominal wall with an antiseptic solution (sterile preparation).
- 3. Mark entry and exit points with the surgical marker (Fig. 233-5). Confirm acceptability of location with the patient before proceeding. Use the crest of the navel fold as a guide. On the abdominal wall, mark the entrance site at a distance half the length of the curved barbell or the diameter of the ring from the edge of the skin fold. On the undersurface of the navel skin fold, mark the exit site at the same distance from the edge of the fold as the entrance site. This is above the deep, flat base of the umbilicus. Have the patient lie, sit, stand, protrude, and retract the abdomen to evaluate placement of the markings as they vary with each position. Make adjustments in the markings if needed. If an umbilical hernia or other anatomic variants are present, a navel piercing should be avoided.

TABLE 233-2 Average Healing Locations	Times for Piercing
Location	Healing Times
Ear lobe	4–6 wk
Ear cartilage	2–3 mo
Eyebrow	6–8 wk
Nostril	2–3 mo
Nasal septum	4–6 wk
Tongue	4–6 wk
Labret	6–8 wk
Nipple (female)	2–3 mo
Nipple (male)	2–3 mo
Navel	6–10 mo
Clitoral hood	4–6 wk
Penis (Prince Albert)	4–6 wk

**Figure 233-4** Instrument tray. Items shown: gloves, marking pen, cotton applicators, calipers, gauze, captive bead ring, piercing needle, insertion taper, Pennington forceps, and rubber bands. All items are appropriately sterilized. (Courtesy of Armando Escajeda, Jr.)

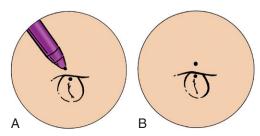

**NOTE:** Our preferred method is to start with the patient in a supine position and mark the exit hole within the fold of skin over the navel. Have the patient stand, and evaluate tissue above the navel fold for a natural indentation. Mark this site as the entrance hole. Choose the appropriate jewelry size ( $\frac{1}{16}$ ,  $\frac{1}{12}$ ,  $\frac{1}{16}$ , or  $\frac{1}{16}$ ) to match the navel's anatomy as determined by the placement of the markings.

- 4. Place rubber bands on the forceps and adjust the tension. Grasp and tent the skin with traction. Avoid actually clamping the forceps because this will crush the skin (Fig. 233-6).
- 5. Position the piercing needle perpendicular to the tented skin and parallel to the floor and the markings (Fig. 233-7).
- 6. Pass the needle through the skin. Remove the forceps. Attach the jewelry to the nonpointed end (see Fig. 233-2) of the needle, then pass the jewelry into the piercing. For a captive ring, the ring needs to be twisted back and forth to allow easy transfer (Fig. 233-8). After the ring is in place, straighten the ring and insert the ball (Fig. 233-9).
- 7. Remove the antiseptic cleansing agent with sterile saline.

#### Other Piercings

#### Ear Lobe

- 1. Cleanse the front and back of the lobe.
- 2. Mark the front and back in the center of the lobe.
- 3. Use the Pennington forceps to stabilize the lobe when passing the needle. Do not ratchet down the forceps. (Disposable ear piercing kits are also available.)
- 4. Pierce perpendicular to the plane of the lobe.

**Figure 233-5** A and **B**, Schematic representation of the skin markings for umbilical piercing. The longitudinal line in the circular area represents the base of the umbilicus. The transverse line represents the navel skin fold. The area between the longitudinal and transverse lines represents the undersurface of the skin fold. The markings are usually equidistant from the edge of the fold.

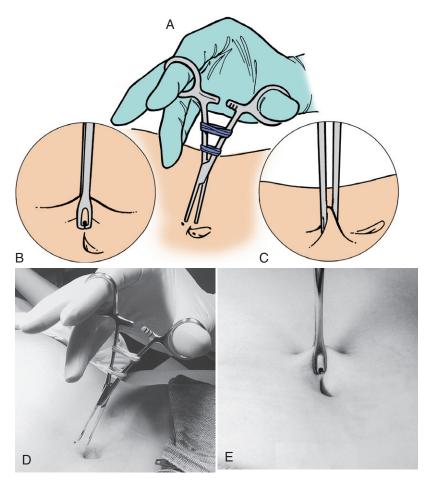

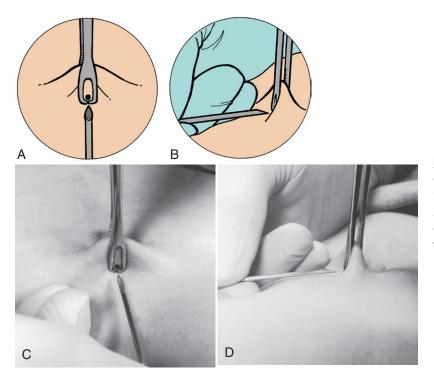

Figure 233-6 Schematic representation of forceps application for umbilical piercing. The patient is supine. A, The navel skin fold has been marked (center). (Note markings above and below the marked skin fold.) The forceps have two rubber bands in place for tensioning. The skin fold will be gently held by the forceps. B, The markings are positioned at the edge of the clamp opening. The skin fold is then gently tented and held perpendicular to the floor. It is important not to engage the clamp's ratchets. C, Forceps application. The skin fold is gently tented and held perpendicular to the floor. Note the deep aspect of the umbilicus is not involved in the piercing. D, Photograph of step A. E, Photograph of step B.

**Figure 233-7** Schematic representation of the needle position for umbilical piercing. **A,** With the skin gently tented, the needle is positioned perpendicular to the skin and parallel to the floor. The direction of the piercing is cranial to caudal (i.e., the needle is pointing toward the foot). **B,** The needle is positioned perpendicular to the skin fold and parallel to the floor. The needle is aligned with the markings and is pointing cranial to caudal (i.e., toward the foot). **C,** Photograph of step A. **D,** Photograph of step B.

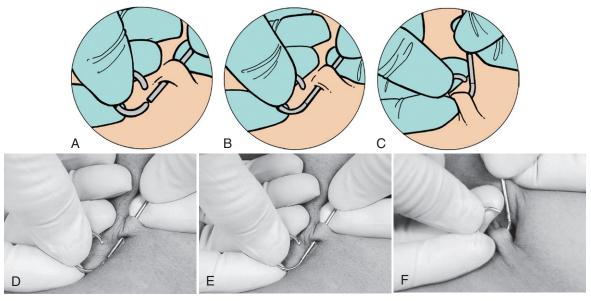

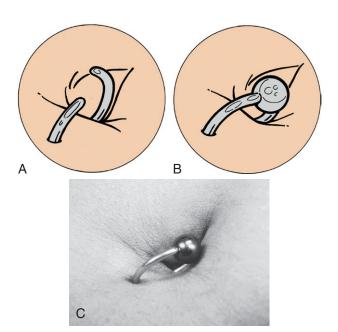

Figure 233-8 Schematic representation of jewelry transfer for umbilical piercing. A, The sharp end of the needle is held with the fingers of one hand. The point can be protected with a cork. B, The jewelry is positioned against the nonpointed end. C, The skin fold is stabilized against the finger during transfer. The jewelry is gently twisted to help clear the skin fold. D, Photograph of step A, showing jewelry positioning. The sharp end of the jewelry is held with the fingers of one hand. The jewelry is being placed on the nonpointed end of the needle. The jewelry is gently twisted to help clear the skin fold. E, Photograph of step B. The jewelry abuts the nonpointed end of the needle. The skin fold is stabilized against the finger holding the sharp end. F, Photograph of step C showing jewelry transfer. The jewelry has been transferred through the skin fold. During the transfer, the jewelry is held against the nonpointed end of the needle. The jewelry is gently twisted to help clear the skin fold.

#### Ear Cartilage

- 1. Clamping is not recommended for cartilage because of potential crushing and increased risk of complication.
- 2. Use a free-hand technique or a needle-receiving tube.
- 3. Pierce perpendicular to the plane of the cartilage.

**Figure 233-9** Schematic representation of jewelry for umbilical piercing. **A**, The ring has a gentle twist and must be untwisted for bead placement. **B**, The bead has indentations, and these are positioned between the ends of the ring. **C**, The captive bead ring is positioned in the navel's skin fold.

#### Eyebrow

- 1. Can be performed similar to the navel technique.
- 2. The piercing is placed over the lateral third of the eyebrow to avoid the supraorbital nerve.
- Slant the piercing toward the nose with the lower mark made medial to the upper mark.
- 4. Avoid a shallow piercing because this can lead to migration.

#### Nostril

- 1. The entrance point is at the natural indentation of the alar fold; the direction of the piercing is external to internal.
- 2. Use a needle-receiving tube placed inside the nostril to avoid tissue damage.
- 3. Avoid using a clamp on the ala because this will crush the cartilage.

#### Nasal Septum

- Piercing is done through the soft membrane inferior to the nasal cartilage.
- 2. The piercing is located ¾ inch from the external tip of the nose and ⅓ inch below the cartilaginous edge.
- 3. Use a needle-receiving tube to stabilize the septum.

#### Labret or Lip

- 1. These are unique piercings because they involve two different tissue surfaces, facial skin and the mucosa of the oral cavity.
- The piercing site in the skin is usually placed below the vermillion border of the lip.
- On the mucosal surface, the site is positioned so the jewelry does not rest on the gums.
- 4. Appropriate jewelry for these piercings are rings or labret studs (see Fig. 233-1). Jewelry size is 3/8 to 1/2 inch.

#### Cheek

 Before the piercing, use a penlight to identify vascular structures, particularly the branches of the facial artery and vein. This will help avoid the branches of the facial nerve.

- Pierce through the facial skin anterior to the laugh line into the oral cavity.
- 3. Inside the oral cavity, the hole should avoid the parotid duct.

#### Tongue

- Choose a central and midline location in the natural bend of the tongue. Have the patient cup the tongue to find this indentation.
- 2. The exit site is anterior to the frenulum. Avoid the veins that are easily visualized on the underside of the tongue.
- 3. Use gentian violet to mark the entrance and exit sites. With the tongue in an extended position, the entrance and exit sites should be perpendicular. This allows for a slightly angulated position when the tongue is retracted.
- 4. During the piercing, hold the tongue in an extended position with gauze or a sponge forceps.

#### Nipple

- The horizontal axis is preferred for women, but they may prefer the piercing to be vertical. The horizontal or vertical axis can be used for men.
- 2. For women, the piercing is placed through the base of the nipple at or just below the midline. In men, placement is at the junction of the nipple with the areola at or just above the midline.

#### Clitoral Hood

Actual clitoral piercings are rare, and they depend on the size of the clitoris. Damage to the neural tissue can occur. Most patients who request a clitoral piercing actually desire the clitoral hood piercing.

#### **VERTICAL PIERCING**

- 1. Find the apex of the hood at the base of the clitoris.
- 2. Mark the outer skin of the hood at this site.
- Measure the distance to the edge of the hood and to the head of the clitoris. Choose a jewelry size that allows the ball to rest on the head. Typically the jewelry will be a ½-inch curved barbell.
- 4. Insert the jewelry; the preferred jewelry is a curved barbell.

#### **HORIZONTAL PIERCING**

- 1. Pierce through the clitoral hood tissue at a similar distance from the clitoris as in the vertical piercing.
- 2. Avoid the veins that pass down the hood; use a penlight to identify the veins.
- Use lightweight jewelry because the weight of the jewelry can pull the hood beyond the clitoris, and the desired effect will be lost.

#### Penis (Prince Albert)

- 1. This is the most commonly requested penile piercing.
- 2. Place the piercing in the thin, soft, triangular skin on the ventral side of the penis just below the corona of the glans at the frenulum.
- 3. Evaluate the penis in both a flaccid and an erect state to locate the entrance site that accommodates an erection.
- 4. Choose the jewelry size based on the erect state of the penis; the jewelry is generally \% to \% inch long.
- 5. Mark the entrance site at the frenulum.
- 6. Place a needle-receiving tube through the meatus into the urethra. Position the end of the tube (which is now inside the urethra) at the entrance site.
- 7. Pass the needle through the skin into the receiving tube.
- 8. Remove the tube and protect the sharp end of the needle with a cork.
- 9. Position the jewelry on the needle and transfer.

**NOTE:** The Prince Albert has a tendency to bleed for several days after the piercing.

#### **COMPLICATIONS**

#### General

Some complications are inherent in all piercing procedures.

- The most common complication is infection from staphylococcal or streptococcal species. Bacterial infections can occur because of improper piercing technique or poor hygiene. Local infections can be cared for using warm compresses, antibacterial soap, and topical mupirocin. In severe skin infections, oral antibiotics such as the first-generation cephalosporins (i.e., cephalexin, cefadroxil, dicloxacillin) may be indicated and are appropriate treatment options for more serious wound infections. If *Pseudomonas* is suspected, use ciprofloxacin. If methicillin-resistant *Staphylococcus aureus* is suspected, consider oral trimethoprim/sulfamethoxazole (Bactrim).
- Other infection: Tuberculosis, tetanus, hepatitis, HIV infection, and toxic shock syndrome have been attributed to contamination at the time of piercing. Genital piercings increase the risk of hepatitis and HIV infections from sexual contact because of the open wounds and associated trauma.
- Pain.
- Bleeding.
- Hypertrophic scarring.
- Keloid formation.
- Granuloma or cyst formation.
- Migration or expulsion of jewelry.
- Contact dermatitis or other skin reaction.
- Possible social stigma.

#### **Specific Complications by Location**

#### Navel

- Migration
- Frictional irritation
- Scar formation

#### Ear Cartilage

- Associated with poor healing and more serious infection because of the avascular nature of auricular cartilage
- Auricular perichondritis and perichondrial abscess (typically occur in the first month after piercing, especially during warmweather months)
- Infection from Lactobacillus, Pseudomonas more common
- Toxic shock syndrome (very rare)
- In one study, 34% of ear piercings experienced complications such as mild infection, pain, and allergic reaction

#### Ear Lobe

- Keloids, especially in black individuals
- Enlargement of the opening and traumatic lacerations tearing through the lobe
- Lack of symmetry between the two sides

#### Eyebrow

- Periorbital infection
- Damage to supraorbital nerve

#### Nostri

- Damage to cartilage
- Infection (staphylococcal)

#### Nasal Septum

· Pressure necrosis of cartilaginous border and alae

#### **Tongue**

- Damage to dentition and gums
- Loss of bone supporting the teeth
- Lingual nerve damage
- Hematoma
- Aspiration of jewelry

#### Labret and Lips

Damage to dentition and gums

#### Cheek

- Damage to parotid duct branches of the facial artery, vein, and nerve
- Uncontrolled drooling

#### Nipple

- Interference with lactation
- Mastitis and abscess formation

#### POSTPROCEDURE PATIENT EDUCATION

Advise the following:

- Always wash hands thoroughly before touching the piercing.
- Avoid tight clothing that can cause increased friction at the piercing site.
- Expect serosanguineous fluid to ooze and crust around the entrance and exit sites. This crusting will last until the piercing has completely healed. Only when the crusting has stopped can jewelry exchange or a stretching procedure be considered. The crusted material harbors bacteria and needs to be removed. Soak the piercing site with a warm sea salt solution (¼ teaspoon of sea salt in 8 oz of distilled water) using a soft cloth, gauze, or an inverted glass for 5 to 10 minutes. Then remove the crusted material with a clean, damp cloth or cotton-tipped applicators before carefully twisting the jewelry in the moistened area to ensure it is not trapped.
- Use a mild antibacterial soap that does not contain fragrances.
   We prefer Provon (GOJO Laboratories, Akron, Ohio) and Septicare (Sage Laboratories, Hudson, NH). If using soap, lather the area and the jewelry, then rinse well with water. Allow to air dry. If using Septicare, allow it to dry without rinsing.
- If redness and swelling develop, use warm compresses four times a day for 24 hours. If the redness and swelling do not go away or if a purulent discharge (pus) develops, see a physician.
- For tongue piercings, use an antibacterial mouthwash that does not contain alcohol or a saline solution after meals and smoking. Gargle for 30 to 60 seconds. It is preferable to avoid smoking. Use a new toothbrush and change it every 30 days. Brush the jewelry with the toothbrush to remove plaque.
- Do not use antibacterial ointments such as polymyxin B sulfate, neomycin sulfate, and bacitracin (Neosporin); bacitracin; or polymyxin B sulfate and bacitracin zinc (Polysporin). These ointments are petroleum based and can occlude the piercing. Occlusion will trap serosanguineous fluid and dead cells, delay healing, and promote possible infections. Prolonged use of antibacterial ointments can also irritate the skin. If necessary, prescribe mupirocin (Bactroban) ointment for the first 24 to 48 hours if mild redness or swelling develops. Rub the ointment gently on the jewelry and the surrounding skin until a thin, invisible layer is present.
- Avoid using alcohol, which can dry the skin and the cells involved in healing the piercing.
- Avoid using hydrogen peroxide and povidone-iodine, which are toxic to healing tissues.

#### **CONCLUSION**

Body piercing is an elective procedure that patients may be surprised to learn a physician understands and can perform. Anatomic evaluation, aseptic technique, appropriate aftercare, and proper selection of jewelry to fit the location are keys to a successful piercing procedure. Understanding the patient who requests a piercing is necessary to obtain an excellent result.

#### **PATIENT EDUCATION GUIDES**

See the sample patient education and consent forms online at www.expertconsult.com.

The following brochures are available from the Association of Professional Piercers (APP) (www.safepiercing.org). The APP has also written the APP Procedural Manual.

- Picking Your Piercer
- Aftercare Guidelines for Facial and Body Piercings
- Aftercare Guidelines for Oral Piercings
- Body Piercing Troubleshooting: For You and Your Healthcare Professional

#### **BILLING AND CODING**

Because this is a cosmetic procedure, providers need to collect payment directly from the patient. However, there is an ICD-9 code for ear piercing (V50.3).

# INTERVENTIONAL PROCEDURES FOR HEADACHES: ACUTE AND PREVENTATIVE

Duren Michael Ready

Headaches are an almost universal condition. They are as old as humankind. Headache management evolved beyond "taking two aspirins" with the development of the ergots and migraine-specific triptan medications. Physicians frequently still encounter patients who have broken through their prophylaxis, failed acute treatments, and are in need of rescue therapies.

The introduction of sumatriptan and the subsequent development of additional triptans have proven to be a great enhancement for the acute and rescue treatment of migraine and cluster headaches. Triptans are still considered to be underused medications. However, even they have their limits. They work best when used at the onset of mild pain and are of very limited utility 24 hours after onset of the headache. Unfortunately, when we encounter many of these difficult patients, it is too late to use them.

Several of the procedures discussed here are older (greater and lesser occipital nerve blocks and sphenopalatine nerve blocks) and well established in the medical literature. However, newer techniques (botulinum toxin and paracervical intramuscular spinal blocks) are under increasing study and use.

There are multiple benefits to incorporating injection procedures into the management of headaches. They can provide some of the fastest relief (occipital nerve blocks, paracervical intramuscular spinal blocks), are the most comfortable (sphenopalatine ganglion blocks), and the most beneficial to patients with refractory headache (botulinum toxin). They are relatively simple, easy to learn, and provide a great deal of patient satisfaction.

An additional benefit to using injection procedures for acute or rescue management of headaches is to stem the use of narcotics. A recent study surveyed Canadian emergency department acute headache treatments and reported that over half of patients had their first exposure to narcotics in the emergency department as a rescue therapy. There has been a growing consensus among physicians treating headaches that narcotics should be used, if at all, only as a last resort. This is because of their almost universal tendency to sensitize the central nervous system and ultimately make the headaches refractory to treatment.

A history and physical examination are essential before initiating treatment to rule out any "red flags" for secondary headaches that are caused by treatable conditions. Usually the history will reveal a primary headache disorder that allows for a satisfactory treatment plan. But it is also important to discover potential contraindications to these procedures, such as prior cranial surgery. The physical primarily identifies secondary causes of headaches. In primary headache disorders such as migraine or tension-type headache, the physical examination is usually unrevealing (Table 234-1).

Most patients have sought help only after they have failed their usual prophylaxis and available acute treatments. Although pharmacologic interventions are still an option, procedural treatments for the most part are simple and safe, and they can be a beneficial asset for the treatment and prevention of many headache disorders. In this chapter, we discuss lower cervical intramuscular blocks, occipital nerve blocks, sphenopalatine ganglion blocks, and botulinum toxin injections.

Also, see Chapter 8, Peripheral Nerve Blocks and Field Blocks, Chapter 9, Oral and Facial Anesthesia, and Chapter 56, Botulinum Toyin

## LOWER CERVICAL INTRAMUSCULAR INJECTIONS

In 2006, Mellick and colleagues reported a 1-year retrospective review of lower cervical intramuscular injections in over 400 emergency department patients treated for headaches. The results were impressive: 65.1% had resolution within 15 minutes and an additional 20.4% had partial relief within 20 minutes. When patients who were not pain free 20 minutes after treatment were reinjected, additional improvement was seen in 59.5% of the patients. The study did not attempt to differentiate between headache subtypes, so the procedure can be tried with most headaches.

#### **Anatomy**

Landmarks to identify include the spinous processes of T1, C6, and C7. The injections are placed 2 to 3 cm lateral to the midline either at the level of C6 or C7, so there is some latitude as to their placement. Although there are no major arteries in the area it is always a good practice to aspirate before injections.

#### **Indications**

Although indications have not been well established, generally this procedure is beneficial for migraine, tension-type, post-traumatic, and cervicogenic headaches.

#### **Relative and Absolute Contraindications**

Secondary headache disorders are a relative contraindication (see Table 234-1). Treatment of the headache should not interfere with treatment of the underlying condition. Allergy to the local anesthetics is also a contraindication.

TABLE 234-1 Red Flags for Acute Secondary Headache Disorders			
Red Flag	Differential Diagnosis	Possible Work-up	
Headache beginning after 50 years of age	Temporal arteritis, mass lesion	Erythrocyte sedimentation rate, neuroimaging	
Sudden onset of headache	Subarachnoid hemorrhage, pituitary apoplexy, hemorrhage into a mass lesion or vascular malformation, mass lesion (especially posterior mass)	Neuroimaging; lumbar puncture if neuroimaging is negative*	
Headaches increasing in frequency and severity	Mass lesion, subdural hematoma, medication overuse	Neuroimaging, drug screen	
New-onset headache in a patient with risk factors for human immunodeficiency virus infection or cancer	Meningitis (chronic or carcinomatous), brain abscess (including toxoplasmosis), metastasis	Neuroimaging; lumbar puncture if neuroimaging is negative*	
Headache with signs of systemic illness (fever, stiff neck, rash)	Meningitis, encephalitis, Lyme disease, systemic infection, collagen vascular disease	Neuroimaging, lumbar puncture, † serology	
Focal neurologic signs or symptoms of disease (other than typical aura)	Mass lesion, vascular malformation, stroke, collagen vascular disease	Neuroimaging, collagen vascular disease evaluation (including anti-phospholipid antibodies)	
Papilledema	Mass lesion, pseudotumor cerebri, meningitis	Neuroimaging, lumbar puncture <sup>†</sup>	
Headache subsequent to head trauma	Intracranial hemorrhage, subdural hematoma, epidural	Neuroimaging of brain, skull, and, possibly,	

<sup>\*</sup>Lumbar puncture may follow a negative neuroimaging procedure if suspicion of hemorrhage, infection, or malignancy remains high.

From Newman LC, Lipton RB: Emergency department evaluation of headache. Neurol Clin 16:285-303, 1998.

#### **Equipment and Supplies**

- Bupivacaine 0.5% 3 mL (1.5 mL injected bilaterally)
- Syringe with 25-gauge, 1½-inch needle
- Gebauer's ethyl chloride (optional vapocoolant spray to minimize injection discomfort)

#### **Precautions**

As with all injections, sterile technique is essential. Inject slowly to minimize risk of a vasovagal reaction.

#### **Technique**

See Figure 234-1.

- 1. Have the patient seated with the neck flexed, chin toward chest. The forehead can rest on crossed forearms.
- 2. Identify the T1 spinous process by finding the superiormost rib. Walk your fingertips medially to the spinous process and move up one or two levels to the C6 or C7 level. Identify the areas for injection bilaterally, 2 to 3 cm lateral to the selected spinous process (two fingerbreadths approximates 3 cm for many people).
- 3. Insert the needle to the hub perpendicular to the cervical spine, toward the anterior neck.
- 4. Once fully inserted to the needle's hub, aspirate, and if there is no return, inject all of the bupivacaine slowly in one spot. After

- all of the bupivacaine is injected, withdraw the needle and apply an adhesive strip (Band-Aid) at the site of the injection.
- 5. Repeat the injection on other side.
- The injection may be repeated once in 20 to 30 minutes if the headache has not resolved.

It is not known whether relief is a function of resolution of muscle tension, reflex arc to the spinal trigeminal nucleus, a combination of the two, or some other mechanism of action.

#### **Common Errors**

The procedure itself is very simple and does not lend itself to many errors.

#### **Complications**

Adverse events are uncommon and limited, but have been reported as muscle soreness at injection sites, transient weakness of posterior neck muscles, and vasovagal reactions.

#### Postprocedure Management

Typically, placement of a bandage is all that is required after an injection; however, if any complications develop they should be managed before patient discharge.

**Figure 234-1** Lower cervical intramuscular injection. **A,** A 25-gauge,  $1\frac{1}{2}$ -inch needle attached to a 10-mL syringe filled with 3 mL of 0.5% bupivacaine is inserted up to the hub into the paraspinous muscles, 2 to 3 cm lateral to the midline at a level between the C6 and C7 spinous processes and at an angle perpendicular to the cervical spine. The bupivacaine is injected slowly to minimize patient discomfort. After 1.5 mL of the bupivacaine has been injected, the needle is withdrawn, the injection site is bandaged, and the procedure is repeated on the other side. **B,** Lower cervical intermuscular injection. The injections are placed perpendicular to the cervical spine, 2 to 3 cm lateral to the area between the C6 and C7 spinous processes.

<sup>†</sup>Suspicion of specific central nervous system infections (e.g., Lyme disease, syphilis) or intracranial hypertension (pseudotumor cerebri) warrants lumbar puncture with cerebrospinal fluid analysis and pressure measurement.

#### **CPT/Billing Code**

20552 Injection(s); single or multiple trigger point(s), one or two muscles

This is a common code for cervicalgia, which is frequently associated with headaches.

## GREATER AND LESSER OCCIPITAL NERVE BLOCKS

The greater and lesser occipital nerve blocks are additional beneficial procedures that are well established and relatively simple to learn. In a study by Ashkenazi and Young (2005), 89.5% of patients with episodic or transformed migraines responded to greater occipital nerve blocks (GONB). The GONB has been used as an acute and a preventative treatment for *migraine*, *cluster*, *and tension-type headaches*. This block is a popular treatment for individuals who need quick relief without sedation, although it is slightly more uncomfortable than the lower cervical intramuscular injection. Patients who describe their headaches as "exploding" typically find the greatest relief. The recent discovery of transcranial sensory nerves connecting the scalp and the dura offers an interesting possibility for a mechanism of action, although the exact mechanism has yet to be defined.

#### **Anatomy**

The greater occipital nerve (GON) rises out of the dorsal primary rami of cervical spinal nerves 2 and 3. It provides cutaneous sensation to the medial posterior portion of the scalp. The lesser occipital nerve (LON) represents the ventral branches of C2 and C3. These origins suggest a possible mechanism of action: a reflex signal transmitted to the spinal trigeminal nucleus through the C2 nerve.

The GON and LON emerge from underneath the muscles at the level of the nuchal ridge. The GON lies about 2 to 3 cm lateral to the greater occipital protuberance and adjacent to the greater occipital artery. Attempt to palpate the greater occipital artery to approximate the GON. The GON is frequently tender to palpation during acute headaches.

#### **Indications**

The GONB is indicated for prevention and treatment of *primary headache conditions and other cephalgias in the back of the neck*. In earlier clinical trials steroids have not been shown to significantly enhance the effectiveness of an ONB, with the noted exception of cluster headaches. When corticosteroids are used, their frequency should be moderated to typically no greater than one every 3 months, with a continuing assessment of individual risks and benefits. If no steroids are used, the risks and benefits of repeated injections of local anesthetic should guide decisions about frequency.

#### **Relative and Absolute Contraindications**

Occipital nerve block is relatively contraindicated in the presence of a bony defect. Patients with a prior occipital or mastoid craniotomy should be injected only by a skilled clinician familiar with the patient to avoid any risk of spinal anesthesia. Caution should also be used in patients with impaired glucose tolerance or diabetes because the steroids may worsen hyperglycemia. In these instances the blocks may be performed with local anesthetic alone.

#### **Equipment and Supplies**

Amounts listed here are for *unilateral* injections. They will need to be doubled for bilateral injections.

- Steroid: typically no more than 1 mL per side.
  - Intermediate-acting, moderate-potency: triamcinolone acetonide 20 to 40 mg (Kenalog 40 mg/mL).
  - Long-acting, high-potency: dexamethasone 4 mg (Decadron 4 mg/mL)
- Local anesthetic: 0.5% bupivacaine 3 mL.
- Local anesthetic: 1% lidocaine with or without epinephrine (optional). If lidocaine is used, the patient may report onset of the anesthetic effects of the block while it is still being administered, thereby making the block more tolerable.
- 10-mL syringe with a 25-gauge needle
- The desired quantity of steroid is drawn up into the syringe using a 20-gauge needle and sterile technique, followed by the desired quantities of the bupivacaine or lidocaine. The total volume should be 3 to 4 mL of solution for a unilateral block and 6 to 8 mL of solution for a bilateral block.

#### **Precautions**

Always confirm a patient's allergies to medications before any procedure.

#### **Procedure**

Many techniques have been reported in the literature, but this is no comparison study of the merits of one injection technique over another. It appears best to block the GON and LON by inserting the needle between them and advancing it toward the respective nerves (always aspirating before injection), thereby providing a block that is complete over the superior nuchal ridge. Other clinicians have reported success with blocking the GON and LON using two separate injections.

## Greater and Lesser Occipital Nerve Block with One Injection Site

See Figure 234-2.

- 1. Have the patient lean forward with the chin flexed forward toward the chest and the head resting on the forearms.
- Identify the superior nuchal ridge from the medial greater occipital protuberance to the lateral mastoid process. Attempt to palpate the greater occipital artery.
- Introduce the needle between the approximated GON and LON and advance to the skull, withdraw the needle slightly, and administer a small bolus of the solution.
- Advance the needle medially toward the GON (staying above the nuchal line), aspirate, and inject approximately 2 mL of solution.
- 5. Withdraw the needle and redirect toward the mastoid process, aspirate, and inject the remaining solution.
- Repeat the procedure on contralateral side if the headache is bilateral.

## Greater and Lesser Occipital Nerve Blocks as Individual Injections

In this variation of the GONB, the GON and LON are blocked by two separate injections placed medial and lateral to the anatomic position of the GON and LON.

- 1. Have the patient lean forward with the chin flexed forward toward the chest and the head resting on the forearms.
- 2. Identify the greater occipital protuberance at the midline.
- 3. Inject approximately 2.5 cm lateral to the greater occipital protuberance, just medial to the palpable greater occipital artery. Advance the needle at a slight angle toward the vertex until it strikes the skull. Now withdraw the needle slightly, aspirate, and inject around the target (medially and laterally by approximately 0.5 mm).

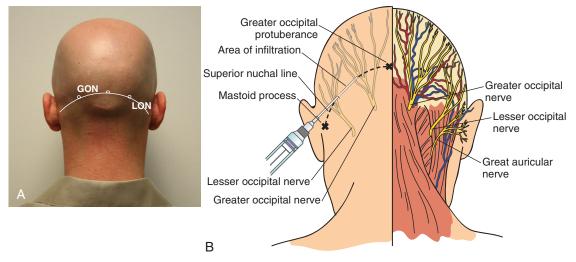

Figure 234-2 A, Occipital nerve block. An imaginary curvilinear line is drawn over the superior nuchal line between the greater occipital protuberance and the mastoid process. The line is then divided into thirds. The medial division represents the approximate position of the greater occipital nerve (GON). The lateral division represents the position of the lesser occipital nerve (LON). Injections may be placed over the GON and LON. B, Occipital nerve block. An imaginary curvilinear line is drawn over the superior nuchal line and directed toward the GON and LON. B, Occipital nerve block. An imaginary curvilinear line is drawn over the superior nuchal line between then greater occipital protuberance and the mastoid process. The line is then divided into thirds. The medial division represents the approximate position of the GON. The lateral division represents the position of the LON. Injections may be placed over the GON and LON (their approximate position [i.e., nerve sites] as labeled on the imaginary curvilinear line), or the injections may be placed between the nerves (marked by the Xs) at the superior nuchal line and directed medially toward the GON and then redirected laterally toward the LON. (B, From Cousins MJ, Carr DB, Horlocker TT, Bridenbough P [eds]: Cousins and Bridenbough's Neural Blockade in Clinical Anesthesia and Pain, 4th ed. Philadelphia, Lippincott Williams & Wilkins, 2008, p 421.)

- 4. Place the second injection an additional 2.5 cm lateral to the previous site, approximately two thirds of the distance along a line drawn from the greater occipital protuberance to the mastoid process. As before, the needle is directed in a slight angle toward the vertex, advanced until contact is made with the skull, and withdrawn slightly; then aspirate and inject in a trigger-point manner.
- 5. Repeat on contralateral side if needed.

#### **Common Errors**

Intra-arterial injection of local anesthetic can usually be prevented by aspirating before injection.

#### **Complications**

In addition to the complications reported for lower cervical intramuscular injections, the following may arise:

- As with any repeated steroid injection, it has been suggested that
  the patient may develop Cushing's syndrome or fatty atrophy
  at the injection site (see Chapter 192, Joint and Soft Tissue
  Aspiration and Injection [Arthrocentesis]).
- It has been suggested that a seizure may result from intra-arterial injection of the local anesthesia; aspiration before injection will prevent this adverse event.
- Spinal anesthesia has been reported with ONB in a patient with a history of prior cranial surgery. In such patients, it would be best not to perform these procedures unless absolutely necessary, and then only with great caution and appropriate resources. If spinal anesthesia does occur, support the patient until the condition resolves (until the local anesthesia has worn off). The patient may need to be transported to an emergency department or hospital until recovery occurs. The reported cases of spinal anesthesia all occurred in individuals who have bony anomalies or prior craniotomies, and all recovered once the effects of the local anesthesia had resolved.

#### Postprocedure Management

Postprocedure management is primarily limited to observation of the patient to see if the headache has resolved and to offer additional treatment if needed. If the patient had a vasovagal response, a brief period of observation is appropriate.

#### **CPT/Billing Code**

64405 Greater occipital nerve blocks

No specific code exists for lesser occipital nerve blocks. Consider using 64450: Injection, anesthetic agent, other peripheral nerve or branch. You can also charge for the steroid using J-Codes (see Chapter 192, Joint and Soft Tissue Aspiration and Injection [Arthrocentesis]).

Some insurance companies may consider ONBs investigational or experimental, so it will be important to document the need for the injection in the patient's chart. These reasons could include failure to respond to more conservative therapies, prior positive response, or the acute need for the procedure. Injections with steroids should be limited to no more than four times a year, typically waiting at least 2 months between injections at the earliest. The Michigan Head Pain and Neurological Institute has reported a patient who was self-administering GONBs about four times a day, so any treatment has the potential for abuse. It is hoped that if any clinician encounters these situations, he or she will consult appropriately.

#### SPHENOPALATINE GANGLION NERVE BLOCK

The sphenopalatine ganglion (SPG) block was first described over 100 years ago by Greenfield Sluder as a treatment for a variety of headaches and facial pain syndromes. The block originally used a cocaine solution. As the medical applications of cocaine came under increasing scrutiny, the procedure became more uncommon. Another likely explanation for the SPG block's fall from favor as a preferred treatment for headaches was the development

of ergotamine derivatives, which provided an easier treatment. In the early 1980s, interest in the procedure returned as headache specialists started to report success treating difficult and refractory cephalalgias. Because the SPG represents a "crossroad" of neurons involved in pain processing, clinicians using SPG blocks have reported its effectiveness in a variety of central pain syndromes, from complex regional pain syndrome to fibromyalgia. A common thread through many of the modern articles about SPG blocks is the question, why is this procedure underused? There are also multiple reports of patients being successfully taught this procedure for self-administration. Although this is a realistic option for some patients, they should be selected carefully on a case-by-case basis.

#### **Anatomy**

The SPG (also known as the pterygopalatine or Meckel's ganglion) is the largest collection of neuronal cell bodies outside the central nervous system. It is located in the pterygopalatine fossa behind the mid-nasal fossa and in front of the pterygoid canal. Physiologically, there are three major roots: motor, sensory, and sympathetic. It connects the trigeminal and facial nerves and communicates directly with the cervical sympathetic ganglia by the deep petrosal nerve. An SPG block potentially blocks three types of nerve fibers: sensory, sympathetic, and parasympathetic. The zygomatic arch can be an important external landmark because it corresponds to the level of the medial turbinate in the nasopharynx (see also Chapter 9, Oral and Facial Anesthesia).

#### **Indications**

The SPG block is indicated for acute migraine, cluster headaches, and facial neuralgias. It may be useful for status migrainosus and chronic cluster headaches. There are reports of varying response to the SPG block for a variety of central pain processes, and given its simplicity and lack of significant adverse events, it is not unreasonable to offer it as a treatment. For central pain conditions (e.g., fibromyalgia, complex regional pain syndrome), it is common to perform several blocks over the space of 1 to 2 weeks.

#### **Relative and Absolute Contraindications**

Contraindications are as described for the previously discussed blocks. In addition, a history of nasopharyngeal neoplasms might allow the local anesthetic to cross to the dura and produce spinal anesthesia. History of epistaxis should signal the examiner to proceed with caution; however, this risk is minimized with the use of topical nasal decongestants. Anatomic anomalies in the nasopharynx (e.g., deviated septum, nasal polyps) may also complicate the procedure.

#### **Equipment and Supplies**

- Topical, over-the-counter nasal decongestant spray (e.g., Afrin, Neo-Synephrine)
- Sterile cotton swabs (solid wood or hollow plastic)
- 2-inch intravenous catheter (if using the intravenous [IV] catheter technique)
- Local anesthetic: viscous lidocaine 2%, or lidocaine 4% compounded with 1% phenylephrine

#### **Precautions**

Nasopharyngeal cancers that communicate with the dura might lead to a spinal block. There has been a single reported case of respiratory arrest due to spinal anesthesia. The patient had a complete recovery after the local anesthesia had worn off.

#### **Procedure**

The goal is to apply topical anesthesia to the inferior branch of the SPG unilaterally, or bilaterally if needed. Two techniques are commonly described. The traditional technique involves sterile cotton swabs (either wood or hollow plastic—both have advantages that will be discussed). The more recent involves a flexible 1-to 2-inch IV catheter attached to a syringe. A positive response typically occurs in 5 to 10 minutes, although most clinicians keep the applicators in place for 20 to 30 minutes and repeat when necessary.

## Sphenopalatine Ganglion Block with Cotton-Tipped Applicators

See Figure 234-3A and B.

- 1. With the patient sitting, spray nasal decongestant bilaterally.
- Apply local anesthetic (viscous lidocaine or lidocaine with phenylephrine) topically to the mucosa of the nasal vestibule and antrum to minimize patient discomfort.
- Have the patient lie down with a pillow or a towel roll under the shoulders to extend the neck and point the nose toward the ceiling. Allow several minutes for the nasal decongestant and local anesthesia to take effect.
- 4. Identify the zygomatic arch and use it as a landmark for the middle turbinate.
- 5. Pass a lidocaine-saturated cotton-tipped applicator into the nasal antrum. Do not force the swab. If you encounter resistance, wait a moment to allow for greater topical anesthesia to occur and then continue advancing the swab gently. Slowly twisting the swab between your fingers as you progress will also ease passage. Continue advancing the swab posteriorly until contact is made with the posterior pharyngeal wall, and then withdraw slightly. At this point, the swab has been inserted to a depth of about 4 inches (10 cm).
- You may place a second swab unilaterally, posteriorly and superiorly.
- 7. Repeat insertion if needed on the contralateral side.
- 8. Leave the swabs in place for 20 to 30 minutes and then withdraw them slowly while rotating them to increase exposure of the ganglion to the topical anesthetic.

**PEARLS:** Greater exposure to the nasal antrum can be achieved by elevating the nasal apex, thereby opening the nares. Some clinicians have reported additional benefits to rotating the swabs once they are in place, thereby exposing additional anesthetic to the SPG. Some patients are more comfortable having the applicators placed while sitting instead of lying down. One advantage that the hollow plastic swab may have is that once it is in place, small amounts of local anesthesia can be reinstilled through the swab. However, much the same can be accomplished with the wooden swabs by slowly dripping the local anesthetic down the side of the swab. When introducing the additional anesthetic, proceed slowly, using only small amounts to minimize the chance of the patient swallowing the medication. Continued anesthesia can also be accomplished by withdrawing the swabs and replacing them with new ones. Any patient discomfort during the second insertion is greatly diminished because of the preceding anesthesia.

### Sphenopalatine Ganglion Block with Flexible Intravenous Catheter

This technique is primarily for unilateral headaches, so treat the affected side (Fig. 234-3C and D).

- Instill 4 mL of 2% viscous lidocaine in a 10-mL syringe, then attach a 2-inch flexible IV catheter from which the needle has been removed.
- 2. Insert the catheter through the nares toward the posterior nasopharynx, through the middle turbinate.
- 3. Have the patient turn the head to the side of his or her pain.

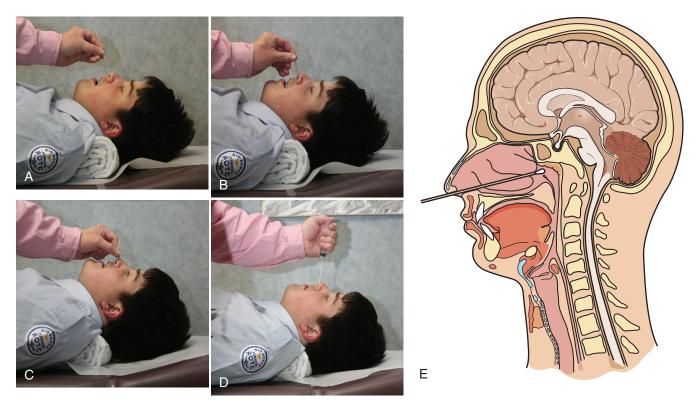

Figure 234-3 Sphenopalatine ganglion (SPG) block. **A,** Step 1: The patient is placed face up with a towel roll under the neck to extend the neck. After applying topical anesthetic to the nasal antrum, the cotton-tipped applicator is introduced into the nostril (targeting the level of the zygomatic arch—the level of the SPG between the first and second turbinates). **B,** Step 2: The cotton-tipped applicator is gently advanced, never forced. A twisting motion of the swab between the fingers may ease passage. **C,** Step 3: The cotton-tipped applicator is advanced until it touches the posterior pharyngeal wall. It is then withdrawn about 1 cm. It is left in place 15 to 20 minutes and replaced if needed. **D,** Step 4: After placement of the applicator, the process may be repeated or additional anesthetic may be applied slowly down the shaft. It will drain down to the cotton tip and replenish the absorbed anesthetic. If a plastic applicator is used, the local anesthetic may be placed inside the hollow shaft. **E,** Diagram demonstrating placement of cotton-tipped applicator in the nasopharynx.

4. Slowly administer 2 mL of the viscous lidocaine while having the patient refrain from swallowing or moving the head. Instill the remaining 2 mL after 10 minutes. If the patient is unable to refrain from swallowing, use the cotton swab applicators.

#### **Common Errors**

 Incorrect placement of the swab not producing adequate blockade; withdraw and replace the swab or try the IV catheter technique

#### **Complications**

- Epistaxis can occur. It is managed in the usual manner.
- Rarely, toxic effects of the local anesthetic might occur as a result of resorption into a very well-vascularized tumor.
- It has also been suggested that in patients who self-administer the SPG block, mucosal erosions might develop, and that this might lead to some spinal resorption of the local anesthetic. This can be prevented by using a nasal rinse such as the Sinus Rinse (NeilMed Pharmaceuticals, Inc., Santa Rosa, Calif) after removal of the cotton-tipped applicator.

#### **Postprocedure Patient Education**

 If posterior pharyngeal numbness develops, the patient should not eat or drink until it resolves, typically within 1 hour.

#### **CPT/Billing Code**

64505 Injection, anesthetic agent; sphenopalatine ganglion

#### **BOTULINUM TOXIN TYPE A**

**EDITOR'S NOTE:** The reader should become totally familiar with the information included in Chapter 56, Botulinum Toxin, as well as the information in this chapter before injecting Botox for the treatment of headaches.

In the early 1980s, Alan Scott was the first physician to use onabotulinumtoxinA (also known as botulinum toxin type A [BTX-A] or Botox) to treat strabismus in humans. To date, BTX-A is the most widely used and studied form of botulinum toxin. It was during clinical trials using BTX-A for treating brow lines that William Binder, an otolaryngologist, discovered that migraineurs receiving Botox injections for wrinkles experienced fewer headaches. Many of these patients reported fewer migraines or total elimination of migraine pain.

When injected locally, BTX-A binds to acceptor sites on motor or sympathetic nerve terminals and inhibits acetylcholine release by cleaving the SNAP-25 component of the SNARE complex responsible for docking and fusion of the acetylcholine vesicles. BTX-A has also been shown to inhibit release of glutamate, substance P, and calcitonin gene–related peptide from nociceptive neurons, thereby providing a secondary mechanism of action different from neuromuscular junction blockade. The effect is temporary (although it should last several months) and is overcome by regeneration of proximal axons and neuromuscular junctions.

At the International Headache Congress at Philadelphia in 2009, David Doddick from the Mayo Clinic reported that the "pooled analyses from the PREEMPT 1 and 2 trials demonstrate that treatment with onabotulinumtoxin A resulted in a highly significant improvements in onabotulinumtoxin A treated patients versus

placebo-treated patients in frequency of headache days in patients suffering from chronic migraine" (www.neurologyreviews.com/09oct/c1botox.html).

Although the PREEMPT 1 and 2 trials have shown promising results for certain refractory headache populations, the use of BTX-A for treatment of headaches remains an off-label use, so there are no standardized protocols for the injection of BTX-A for headaches. Consequently, several different methodologies have been developed.

BTX-A can be used as a treatment for patients with *recurrent* headache, primarily migraines. Because the goal of headache treatment is to reduce their frequency, severity, and associated disability, and improve the patient's quality of life by reducing headache-related distress and symptoms, it is essential to start with an accurate history and diagnosis. As with the previously discussed treatments, it is mandatory to rule out secondary headache disorders.

More importantly than for any of the other headache procedures, informed consent with a discussion of costs and expectations must be obtained. Because the level of coverage can vary significantly from one insurance carrier to another, it is essential to determine if the patient can afford the treatment course before starting. BTX-A is very expensive and a treatment can average around \$500 or more. Documenting prior treatment failure or adverse events to prior therapies can increase the chance of insurance coverage. Improvement may not be noticed for 1 to 2 weeks after injections; in general, improvements are typically seen in 80% of patients.

BTX-A (Botox), manufactured by Allergan, Inc. (Irvine, Calif), is supplied in single-use vials containing 100 or 200 U of vacuum-dried Clostridium botulinum type A neurotoxin complex, 0.5 mg of human albumin, and 0.9 mg of sodium chloride in a sterile, vacuum-dried, preservative-free form. See Chapter 56, Botulinum Toxin, for a description of its use and injection techniques.

#### **Indications**

Ninan Mathew, Director of the Houston Headache Clinic, has suggested that the indications for BTX-A include a lack of improvement with preventive pharmacotherapy; severe and intolerable adverse events from preventive therapy; and patient refusal or inability to use daily medications. Contraindications include acute migraine therapy or an elderly patient with chronic migraine. In 2007, Roger Cady and Curtis Schreiber of the Headache Care Center in Springfield, Missouri, suggested BTX-A as an ideal prophylactic agent for patients with frequent disabling headache who have been poorly controlled with previous preventatives secondary to compliance, adherence, or inability to use conventional preventive therapies as a result of adverse events. In a small study of 63 migraineurs, Jakubowski and colleagues (2006) found that 74% of BTX-A responders described their headaches as a pressure from the outside, imploding, or as an "eye-popping" sensation. Conversely, 92% of the nonresponders described their headaches as "exploding," with pressure building up from the inside.

#### **Relative and Absolute Contraindications**

- Infection at the injection site.
- Known hypersensitivity to any ingredient in the formulation.
- Presence of a neuromuscular disorder (e.g., myasthenia gravis, Eaton-Lambert syndrome).
- BTX-A is labeled category C in pregnancy, and its safety in nursing mothers is unknown.

#### **Equipment and Supplies**

- Botulinum toxin type A
- 1-mL tuberculin syringe

Other gauge needles can be used, but it is generally believed that smaller-gauge needles are less painful.

#### **Precautions**

Because the U.S. Food and Drug Administration has not approved BTX-A for the treatment any headache disorder, it may be prudent to limit the amount of BTX-A to 60 U per session until the patient's response to therapy is known.

#### **Preprocedure Patient Education and Forms**

- Insurance preauthorization forms. Allergan offers physician and patient assistance through their Botox Reimbursement Solutions website (www.botoxreimbursement.us/Home.apx).
- Checklist visit/encounter form (go to www.expertconsult.com).
- Consent forms.

#### **Botulinum Toxin for Headache Prevention**

Three injection paradigms have been used in clinical trials for patients with chronic daily headache and chronic migraine: fixed-site, fixed-dose; follow the pain; or a combination of the two. A study published in Headache demonstrated a positive response with single bilateral injections of 25 U of BTX-A (Behmand and colleagues, 2003).

#### **Basic Tenets**

- 1. Preplan the injections using an anatomic drawing for injection sites and units used (see Chapter 56, Botulinum Toxin, for areas of caution).
- 2. Use a 25-, 27-, 30-, or 31-gauge needle affixed to a tuberculin syringe. Some research has suggested that using a smaller-gauge and slightly longer needle, such as the 31-gauge, 13-mm SteriJect needle, minimizes discomfort and allows for injection of the deeper muscles of the head and neck.
- 3. Inject intramuscularly in a manner that will allow for greater infiltration, avoiding intradermal or periosteal injections.
- 4. In cosmetically sensitive areas, inject in a symmetric fashion.
- 5. Injecting at multiple sites in the targeted muscle group allows for a more even dispersal of toxin through the target region.
- Visualization and avoidance of facial vessels minimizes any subsequent bruising.

#### Preparation

See Chapter 56, Botulinum Toxin.

- 1. Reconstitute the BTX-A and draw up into two syringes (one syringe for each side). Dilution with 2 mL of preservative-free normal saline will yield 50 U/syringe, or 5 U/0.01 mL.
- 2. Return any unused BTX-A to the refrigerator for storage.
- 3. BTX-A must be used within 24 hours of being reconstituted.

#### Fixed-Site Protocol

See Figure 234-4.

- Glabellar region (the area around the smooth prominence between the eyebrows).
  - Smaller fluid volumes minimize spread to adjacent muscles.
  - Inject *procerus* (small muscle that originates at the nasal bone and inserts upward between the eyebrows): Treat as one region, injecting with 2.5 to 4 U.
  - Inject corrugators: Inject two sites bilaterally, totaling four sites, 1.5 to 3 cm apart. The corrugators are identified by having the patient frown. Apply pressure at the supraorbital ridge to reduce the potential for inferior extravasation. Grasping the mid-lateral portion of the corrugators between two fingers while injecting the toxin diminishes risk of eyelid ptosis. See the Precautions section in Chapter 56, Botulinum Toxin.
- Forehead.
  - Inject the frontalis (forehead muscle, anterior aspect of the occipitofrontalis) with a larger volume (20 to 30 U) over a

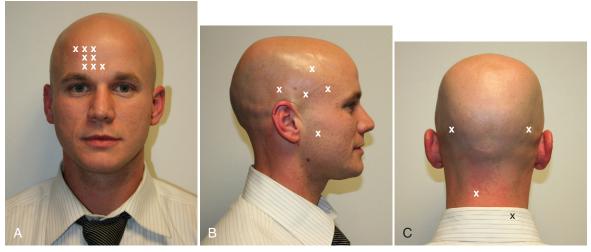

Figure 234-4 Approximate site of botulinum toxin injections over the face (A), temple and jaw (B), and occiput and neck (C).

greater area, typically 8 to 12 sites. Have the patient elevate the eyebrows before injection. Remember to inject symmetrically.

- If the inferolateral frontalis is not painful, do not inject over the lateral third; this will decrease the risk of brow ptosis.
- Lateral injections.
  - If painful, inject the temporalis (large muscle over the temporal fossa). The temporalis is identified by having the patient clench his or her teeth. Injections are given bilaterally, posterior, superior, and inferior, using 0.2 mL per site in four sites, for a total of 20 U.
  - If there is a history of temporomandibular joint syndrome, inject the masseters (large muscle originating from the zygomatic arch and process and inserting into the mandibular ramus and gonial angle) with 5 to 15 U per side.
- Posterior neck muscles.
  - Inject the *trapezius* (bilateral large triangular muscle of the upper back that originates at the occipital bone, ligamentum nuchae, and the spinous processes of C7–T12 and inserts into the distal clavicle, acromion, and scapular spine).
  - If the trapezius is involved or suspected as a pain generator, inject bilaterally at one to three sites with 5 to 15 U total.
  - If posterior neck pain is present, evaluate occipital/cervical paraspinal muscles. Inject one or two sites on each side. The doses varies from 5 to 15 U per side.

## "Follow the Pain" Protocol (Most Commonly Treats Tension-Type Headaches)

- Have the patient identify the areas of origination and radiation of the pain.
- 2. Inject areas associated with pain and tenderness on palpation.
- 3. Inject the identified areas with 4 to 12 U, 1.5 to 3 cm apart.

Common sites of injection include glabellar and frontal regions, temporalis muscle, occipitalis muscle, and cervical paraspinal region. Inject in similar fashion to the fixed-site injections.

#### **Bilateral Single-Site Protocol**

See Figure 234-5. Significant improvement has been reported with single bilateral injections into the corrugator supercilii muscles with 25 U of BTX-A using a 1-inch, 30-gauge needle. Patients were asked to frown to identify the most lateral attachment of the corrugator supercilii muscle. The needle was then inserted at this most lateral attachment and advanced medially toward the root of the nose. BTX-A was then infiltrated evenly across this path as the needle was withdrawn. Be sure to avoid areas where major nerve branches

are present, such as the supraorbital nerve; if injected, significant paralysis may result (see Chapter 56, Botulinum Toxin).

#### **Common Errors**

To avoid a ptosis, avoid injecting lateral to the pupil in an area 1 cm superior to the supraorbital rim, out to the lateral eyebrow. Only time will correct this error; typically, ptosis may take upward of 3 months to resolve.

#### **Complications**

- Most commonly involve bruising and swelling.
- Some patients develop a transient headache that usually resolves within 24 to 48 hours.
- Occasional flulike symptoms may develop and resolve within a day or two.
- A transient ptosis may develop that will resolve over 3 months.
  This is best avoided by not injecting over the lateral supraorbital
  muscles. However, if this is an area of pain, this complication
  may be unavoidable, but it will be essential to warn the patient
  that a ptosis may result.
- Muscle paralysis at site of injection may occur (although this is a desired effect for the most part).
- There have been reports of antibody formation in patients treated with BTX-A for cervical dystonia or torticollis. These procedures used an older, "less clean" formulation of BTX-A in much higher doses than those used for treating migraines. To prevent antibody formation, current recommendations are to limit BTX-A administration to a minimum of 3-month intervals between injections, with an annual load of 300 to 600 U/year.

**Figure 234-5** Single-site botulinum toxin type A (BTX-A) injection. Insert the needle at the designated site over the medial brow and advance toward the target on the medial aspect of the procerus. Slowly infiltrate the 25 U of BTX-A while withdrawing the needle to evenly dispense the drug.

#### **Postprocedure Management**

Remind patients that improvement is gradual and mostly cumulative over several sessions.

#### **Suppliers**

See contact information online at www.expertconsult.com.

Botulinum toxin type A

Tuberculin syringe 1 mL
Air-Tite Products Company

## POSTPROCEDURE PATIENT EDUCATION FOR ANY TREATMENT

It will be important to maintain a headache diary to provide objective measures for determining effectiveness of treatment and direction for future treatments. The goal of most preventive treatments for headache is a 50% reduction in the frequency and severity of the headaches. In the absence of headache diaries, this is very difficult to quantify. If any postinjection wheals or blebs develop, inform the patient that they usually resolve within 2 hours. There may be a reduction in hyperfunctional lines of the face. This should be expected and is not considered an adverse event. It may take several weeks for headache relief, and the greatest benefit is seen with repeated treatments.

## COMMONLY USED INSTRUMENTS AND EQUIPMENT\*

John L. Pfenninger

Listed here are the most commonly used instruments in a primary care physician's office. This list provides a basic beginning for ordering equipment for the office. A physician can alter the equipment depending on the procedures performed.

#### Anoscope

 Every primary care office must have an anoscope to evaluate anal complaints. The Ive's slotted anoscope is recommended, although others are acceptable (see Chapter 98, Anoscopy).

#### Biopsy instruments (skin, cervix, endometrial, colon, breast)

- Skin: 2-, 3-, 4-, 5-mm disposable punches are inexpensive and stay sharp. They are preferable to the reusable Keyes punches (noted next). (See Chapter 32, Skin Biopsy.)
- Skin: A set of Keyes reusable punches is also an option for doing skin biopsies (Fig. A-1). However, they become dull quickly. Considering the time it takes to sterilize them and the sharpening costs, it may be advisable to consider the disposable punches.
- Cervical: Mini-Townsend, Baby Tischler, Kevorkian instruments are preferred (see Chapter 137, Colposcopic Examination, Fig. 137-6).
- Endometrial: Reusable Novak and disposable Endocell (Wallach), PipetCuret (Milex), and Pipelle (Unimar, Cooper-Surgical) instruments are useful (see Chapter 143, Endometrial Biopsy).
- Colon/rectum: For flexible sigmoidoscopy, colonoscopy, and esophagogastroduodenoscopy (EGD) procedures, see Chapter 103, Flexible Sigmoidoscopy, Fig. 103-6. The small flexible biopsy forceps used for flexible sigmoidoscopy can be inserted through an anoscope to obtain adequate biopsies without causing excess bleeding. These can also be readily used for the high-resolution anoscopy procedure (see Chapter 99, High-Resolution Anoscopy).
- Breast: Milex breast biopsy needle and Comeco syringe are optional (see Figs. 226-1 and 226-3).

#### Dermal curettes

• Fox type (3-, 4-, 5-, 6-mm reusable; 2-, 3-, 4-, 5-mm disposable) (Fig. A-2): Reusables work well for soft or necrotic tissue such as basal cell carcinomas. However, unless sharpened regularly, they perform poorly for more fibrotic tissue such as with warts. On the other hand, the disposables are so sharp that they readily cut through any tissue so, if used for curetting out a basal cell, they may actually cut into normal tissue. It is advisable, then, to have both types of curettes.

A disadvantage of using the disposables for larger very

fibrotic lesions is that they bend. An excellent addition is the

Curetteblade. The curette is disposable so it stays sharp, and it fits on a scalpel handle. It is stronger and does not bend under pressure (see Chapter 32, Skin Biopsy, Fig. 32-2C).

#### Forceps

- Adson forceps with and without teeth,  $4\frac{1}{4}$  inches (Fig. A-3)
- Splinter (Fig. A-4)
- Allis (Fig. A-5)
- Uterine packing (look like long, large hemostats)
- Ring (sponge)

Ring forceps can grasp tissue or clot during gynecologic procedures, and are useful for holding gauze or cotton to apply solutions (such as antiseptics or acetic acid to the cervix during colposcopy) or to stop bleeding in the vagina or rectum (Fig. A-6).

#### Hemostats and clamps

- Mosquito: 5-inch straight, 5-inch curved (for fine application) (Fig. A-7)
- Kelly: 5½-inch straight, 5½-inch curved (for larger application) (Fig. A-8)
- Towel clips (Fig. A-9)

#### Scissors

- Suture removal (Spencer 3½-inch) (Fig. A-10)
- Suture cutting (William 4½-inch) (Fig. A-11)

Mayo  $6\frac{3}{4}$ -inch (Fig. A-12)

Curved Metzenbaum 5-inch, 7-inch (Fig. A-13)

Fine tissue (iris)  $4\frac{1}{8}$ -inch (Fig. A-14)

Bandage 5½-inch (Fig. A-15)

#### Needle driver 5-inch (9-inch for vaginal/uterine procedures)

Webster serrated jaws

NOTE: This is not the place to save a few pennies. Buy the best needle holders (Fig. A-16). They are often designated as the ones used for plastic surgery repairs. They are well worth it. Do not become frustrated by using the types provided in the disposable sets.

#### Minor surgery pack

- Scalpel handle with metric ruler inscribed on it (Fig. A-17)
- Fine hemostats (2), curved and straight
- 5-inch curved Metzenbaum scissors
- Pick-ups with teeth
- Pick-ups without teeth
- Suture scissors
- Stainless steel basin
- $4 \times 4$  gauze pads (8–10)
- Glass jar for specimen
- Needle driver
- Also have available: sterile fenestrated drapes, appropriate suture, skin marking pens, alcohol wipes, betadine solution, dressings for the wound

<sup>\*</sup>For a full list of supplier information, see Appendix D.

Figure A-12 Mayo 6¾-inch operating scissors.

Figure A-13 Curved Metzenbaum 5- and 7-inch operating scissors.

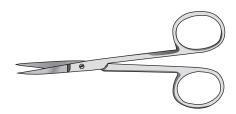

Figure A-14 Fine tissue (iris) 4 1/8-inch scissors.

Figure A-15 Bandage removal scissors.

Figure A-16 Webster serrated jaw needle holder.

Figure A-17 Scalpel handle with metric rule.

**Figure A-18** Madajet SL anesthetic injector. (Courtesy of Mada Medical, Carlstadt, NJ.)

Figure A-19 Seltzer skin hook.

#### Vasectomy setup (no-scalpel)

- Small curved hemostats (2)
- Hemoclip applicator (medium) and clips (or suture)
- Vas dissecting forceps
- Vas clamp (Wilson or Li)
- Sharp tissue scissors
- Battery-powered cautery unit
- Medicine cup
- 4 × 4 gauze pads, large pack
- For the no-needle method, will also need the Madajet anesthetic injector (urology version) (Fig. A-18) (see Chapter 126, Vasectomy)

#### Skin hooks

 Useful for nontraumatic skin or wound edge retraction (Fig. A-19)

#### Staple applicator

See Chapter 34, Skin Stapling.

#### Staple remover

 Removes surgical stainless steel skin staples. Removers are sold as disposable, and many patients have staples, especially after being treated in the emergency room. Staple removers may be reused, however, with appropriate sterilization (Fig. A-20).

#### Syringes

 Clinicians need mostly 1-mL syringes for skin procedures (e.g., biopsies), as well as some 3-mL, a few 5-mL, and even fewer 10-mL (for excisions) syringes. Two 25-mL syringes may also come in handy for thoracenteses, knee aspirations, irrigations, and so forth.

#### Needles (for injection)

**NOTE:** The larger the number, the smaller the needle! Clinicians need mostly  $1\frac{1}{2}$ -inch, 25-gauge and  $\frac{1}{2}$ -inch, 30-gauge needles for skin local anesthesia. The larger 21-gauge and 18-gauge needles are used to aspirate viscous fluid (e.g., ganglions, 18G) or large amounts of fluid (e.g., knee aspiration). Eighteen-gauge needles are also used to draw up anesthetic; it goes much more quickly than with needles that are smaller.

#### 5-inch needle extender

• After twisting the extender on a syringe, the practitioner then locks the needle to this "extender." It is reusable and can be used to reach deep areas like the cervix, posterior pharynx, anus, etc. (See Chapter 149, Loop Electrosurgical Excision Procedure for Treating Cervical Intraepithelial Neoplasia, Fig. 149-4.)

#### Madajet

• A unique instrument for injecting solutions without a needle and with virtually no pain is the Madajet. Each application provides 0.1 mL of liquid for the intended site. It can be used to anesthetize for a simple skin biopsy or used in combination with steroids to treat hypertrophic and keloid scars. It is especially helpful in dense tissue where injecting with a needle is difficult. The instrument is cocked and then activated by pushing a button. This is the same basic unit that has been

Figure A-20 Davis & Geck staple remover.

adapted for the no-needle vasectomy. (Be sure to order the correct device depending on whether it will be used for dermal applications or for vasectomies.) By using small volumes it also prevents distortion of tissue. Extenda Tips are available in varying lengths to reach tissue in the back of the mouth, the rectum, and other areas. It is easily cleaned between patients. Possible indications as listed by the manufacturer include anesthesia for digital block or prior to treating verrucae; steroids for keloids, lichen planus, lichen chronicus simplex, erythema nodosum, and lichen planus; injecting fasciitis, Morton's neuralgia, and more.

#### Suture

- Use cutting needles for the majority of patients: Skin: 3-0, 4-0, 5-0, and 6-0 nylon (for most interrupted skin closures)
- 4-0 and 5-0 Prolene (for subcuticular procedures) Deep inverted: 3-0, 4-0, and 5-0 Vicryl
- See Chapter 24, Laceration and Incision Repair: Suture Selection.

#### Sterile drapes, fenestrated and nonfenestrated

 Both polyurethane and paper drapes are available in solid and fenestrated versions. The area around the fenestration has an adhesive backing to keep it in place. The paper is cheaper but doesn't lie in place as well and can become soiled with blood.

#### Mayo stand with tray to hold instruments

#### Magnification loupes

• Welch Allyn: 2.5× to 3×; has light with battery pack

#### Comedone extractor

Saalfield or Unna types (Fig. A-21)

#### Ear irrigation setup

 A variety of units are available. One of the least expensive (approximately \$40), most effective, and easiest to use is the Elephant Ear Wash System (Fig. A-22).

#### Ear loop curette

 For cerumen removal: Sklar #67-2513. These are available in both reusable metal and disposable, softer plastic. The latter are less traumatic and reduce the discomfort of removing cerumen.

#### For ingrown toenails

- Locke periosteal nail elevator (Fig. A-23)
- Nail splitter (Fig. A-24)

## Chalazion clamp (small) with curette (Figs. A-25 and A-26) Vaginal speculum

- Small, medium, large Graves'
- Nonconductive, vented for loop electrosurgical excision procedure (LEEP)
- Extra long (Snowman by CooperSurgical) for obese patients; very helpful for difficult cases

#### Endocervical curette (Kevorkian, without a basket)

#### Endocervical speculum (small, large)

 For colposcopy and removal of cervical polyps (see Chapter 137, Colposcopic Examination)

#### Cervical dilators (including silver probe)

 For endometrial biopsy, cervical stenosis, and dilation and curettage (D&C) (see appropriate chapters)

#### Dilateria (thin, medium thick, thick)

- For cervical stenosis
- Used to dilate a cervix atraumatically
- See Chapter 136, Cervical Stenosis and Cervial Dilation

#### Word Bartholin cyst catheter

#### Uterine sound

 Malleable rod is used to determine the depth of the uterus (from external os to back wall). Such information decreases the likelihood of uterine perforation during procedures.

#### Vaginal sidewall retractors

 Use for cryotherapy of cervix, LEEP (see Chapter 149, Loop Electrosurgical Excision Procedure for Treating Cervical Intraepithelial Neoplasia)

Figure A-21 Saalfield comedone extractor.

Figure A-22 Elephant ear washer system.

Figure A-23 Locke elevator.

Figure A-24 Nail splitter.

Figure A-25 Desmarres chalazion clamp.

Figure A-26 Skeele chalazion curette.

#### Single-tooth tenaculum for cervix

 Used to stabilize the cervix for intrauterine device (IUD) placement, endometrial biopsy, laminaria insertion, or dilation, or to perform colpocentesis (see Chapter 127, Pregnancy Termination: First-Trimester Suction Aspiration)

#### IUD remover

See Chapter 146, Intrauterine Device Removal

#### Anoscope

- Ive's slotted (see Chapter 98, Anoscopy; Fig. 98-1D)
- Plastic, disposable
- Pediatric

#### McGivney hemorrhoid ligator

 See Chapter 106, Office Treatment of Hemorrhoids; Fig. 106-4

#### Infrared coagulator (Redfield)

- See Chapter 106, Office Treatment of Hemorrhoids; Fig. 106-7
- Used for hemorrhoids, warts, tattoos, nasal turbinates, and bleeders

#### Silver probe

 This small malleable metal probe is basically a thickened wire with slightly bulbous ends. It is used to probe suspected fistulae around the anus and to probe for the cervical canal when the os is stenotic (see Chapter 96, Anal Fissure and Lateral Sphincterotomy and Anal Fistula).

Liquid nitrogen cryogun and Dewar (Brymill, Wallach) for skin

• See Chapter 14, Cryosurgery

Casting supplies

 See Chapter 186, Ankle and Foot Splinting, Casting, and Taping and Chapter 187, Cast Immobilization and Upper Extremity Splinting

Wall blood pressure cuff with stethoscope

Glucose monitor

Oxygen tank on mobile cart

Electrocardiography machine

Pulse oximeter and vital signs monitor (Welch Allyn)

Defibrillator

Banyon Emergency Kit

• See Chapter 220, Anaphylaxis

Electrosurgical coagulation unit (ESU)

- See Chapter 30, Radiofrequency Surgery (Modern Electrosurgery) and Fig. 30-1
- Spend a little more and purchase a high-frequency unit for cutting (Ellman, Wallach, CooperSurgical)

Smoke evacuator for electrosurgical application

See Chapter 30, Radiofrequency Surgery, Fig. 30-1

Cart for ESU unit and smoke evacuator

See Chapter 30, Radiofrequency Surgery (Modern Electrosurgery).

Otoscope and ophthalmoscope

Sharps containers

Safety goggles

Examination tables, powered

 A matter of an inch or two makes a big difference. (Twentyfour inches is the ideal height when the table is as low as it can go. It cannot be higher.)

Examination stools

#### Refrigerator for medications

• Must be separate unit from the one used to store lunches!

Portable DVD player(s) for patient education Binocular microscope

#### **OPTIONAL EQUIPMENT TO CONSIDER**

Air purifier

Colonoscope

See Chapter 100, Colonoscopy

#### Colposcope

• See Chapter 137, Colposcopic Examination, Fig. 137-8

Flexible sigmoidoscope with suction pump and light source, cart

See Chapter 103, Flexible Sigmoidoscopy

#### Gastroscope

- See Chapter 101, Esophagogastroduodenoscopy
- Consider the new thin-diameter versions that do not require sedation.

Halogen flexible floor light or mobile high-intensity ceiling surgical light

Intravenous pole

Nasopharyngoscope

See Chapter 77, Nasolaryngoscopy

Nitrous oxide cryotherapy unit

- See Chapter 138, Cryotherapy of the Cervix, Fig. 138-1
- Tips: 19- and 25-mm flat and slight conical for cervix
- Slanted end tips for skin
- Hemorrhoid tip (multifunctional for skin lesions; virtually never used for hemorrhoids!)

#### Stress electrocardiography unit

See Chapter 93, Exercise (Stress) Testing

#### VE-11 Handzfree anesthetic bottle holder

- See Chapter 4, Local Anesthesia, Fig. 4-1
- Saves time; holds multidose vials of anesthetic; inexpensive

## INFORMED CONSENT

Patrick J. Haddad\*

Before a physician or other health care provider performs any procedure or offers other treatment, the patient and the physician must discuss the reasons for it; the available alternatives; the possible material complications from the procedure or treatment, as well as those from forgoing it; and the patient must consent. Consent is often considered to be simply a form which the patient needs to sign before a procedure or treatment begins, rather than being a process that results in the patient deciding, on an informed basis, whether to accept or reject treatment. Many physicians mistakenly believe or hope that a signed consent form, by itself, will prevent a professional liability lawsuit. However, a consent form alone is not legally sufficient to protect a physician from litigation or from liability if a suit is filed.

#### **LEGAL CONSENT**

A patient's consent to treatment is important to physicians for various reasons, including liability exposure. Physicians have a legal liability exposure to claims for battery and the failure to obtain informed consent. A physician commits battery by treating a patient without consent. Battery is an intentional tort that does not require proof of negligence or of the intent to do harm. Generally, a person commits battery by intentionally touching another individual without consent. The individual may be permitted to recover monetary damages absent bodily injury, although the damages awarded in such circumstances may be nominal. For medical care, consent may be express or implied by the patient seeking treatment or otherwise manifesting consent, or consent may be implied by law, such as in an emergency. If consent is given or implied, however, it is not limitless. A physician remains exposed to liability for battery if the treatment furnished exceeds the boundaries of the consent given or implied.

A patient's consent may be sufficient for a physician to successfully defend a battery claim. However, if the consent, or the patient's refusal of treatment, was not preceded by disclosure of the material benefits, risks, and alternatives, the physician may continue to have a liability exposure, even if the procedure or treatment itself was furnished in a competent manner without technical error or if the procedure was declined. In order for there to be liability for lack of informed consent, the patient generally must show that the physician was negligent, the patient was injured and sustained damages, and the negligence was a proximate cause of the injury and damages. Lack of informed consent is a claim based on professional negligence (i.e., malpractice). Unlike battery, which requires proof of an intentional touching without consent, a negligence claim requires proof of the applicable standard of care and that the physician failed to furnish

\*Mr. Haddad is a member of Kerr, Russell and Weber, PLC, Detroit, Mich. Mr. Haddad is co-chair of the firm's healthcare law practice and is a member of the State Bar of Michigan Healthcare Law Section, the American Bar Association Health Law Section, and the American Health Lawyers Association. This chapter is presented for informational purposes only and does not constitute legal advice by Kerr, Russell and Weber, PLC, or Mr. Haddad. Physicians should consult with legal counsel knowledgeable in the laws of the jurisdictions in which they practice medicine.

care in conformity with that standard, in addition to proof of injury, damages, and causation. The standard of care, and whether the standard has been satisfied or breached, is typically established through the testimony of expert witnesses.

Across the United States, there are generally two alternative ways by which the standard of care is measured when lack of informed consent is alleged. One way is from the perspective of physicians—the reasonable physician standard. Under this standard, timely information must be given to the patient and in accordance with accepted standards of practice among physicians with similar training and experience in the community, or nationally for care furnished by a specialist. This view is followed by a slight majority of jurisdictions in the United States. The alternative view, adopted by slightly less than one half of the jurisdictions in the United States, is from the perspective of patients—the reasonable person standard, under which the patient must be informed of the risks and alternatives that a reasonable person in the patient's position would consider material in deciding whether to accept or to reject the proposed treatment.

Both standards are measured objectively, rather than by the subjective intent of the physician and the patient who are parties to a malpractice suit. Under either standard, risks that are not serious or are remote, or which are already known by the patient or which patients typically know, are generally not considered material.

Adults who are not competent to make decisions about their own health may not give or withold consent, or if they purport to do so, their consent will not be effective legally. Similarly, minor children typically may not consent to medical treatment, although some states have enacted exceptions by statute. For incompetent adults and minors, consent must be obtained from a legal guardian or parent. In emergencies, it is usually permissible to perform procedures or furnish treatment necessary to save the patient's life without consent when it cannot be obtained in a timely fashion.

Some jurisdictions may excuse the obtaining of informed consent when the information might have a detrimental effect on the patient's physical or psychological well-being. The availability and scope of this so-called "therapeutic privilege" can vary among jurisdictions, and physicians should use caution—and consult with legal counsel or with their liability carrier's risk management—before relying on it.

Additionally, physicians need to consider the ethical issues raised by postponing the disclosure of information to patients. Ethically, it may be appropriate in special circumstances to postpone or delay disclosure of certain information if early communication is clearly contraindicated. However, withholding medical information from patients without their knowledge is not ethically permissible. Although all information need not be communicated to the patient immediately or all at once, physicians should assess the amount of information a patient is capable of receiving at a given time.

Some states have codified by statute certain informed consent procedures. Texas, for example, has established panels of physicians and lawyers who together write rules for informed consent for many surgical procedures, including the use of consent forms (Fig. B-1).

State of Texas: 25 TAC §601.4(a)(1) DISCLOSURE AND CONSENT Medical and Surgical Procedures TO THE PATIENT: You have the right, as a patient, to be informed about your condition and the recommended surgical, medical, or diagnostic procedure to be used so that you may make the decision whether or not to undergo the procedure after knowing the risks and hazards involved. This disclosure is not meant to scare or alarm you; it is simply an effort to make you better informed so you may give or withhold your consent to the procedure. I (we) voluntarily request Dr. as my physician, and such associates, technical assistants, and other health care providers as they may deem necessary, to treat my condition which has been explained to me (us) as: I (we) understand that the following surgical, medical, and/or diagnostic procedures are planned for me and I (we) voluntarily consent and authorize these procedures: I (we) understand that my physician may discover other or different conditions which require additional or different procedures than those planned. I (we) authorize my physician, and such associates, technical assistants, and other health care providers, to perform such other procedures which are advisable in their professional judgment. I (we) (do) (do not) consent to the use of blood and blood products as deemed necessary. I (we) understand that no warranty or guarantee has been made to me (us) as to result or cure. Just as there may be risks and hazards in continuing my present condition without treatment, there are also risks and hazards related to the performance of the surgical, medical, and/or diagnostic procedures planned for me. I (we) realize that common to surgical, medical, and/or diagnostic procedures is the potential for infection, blood clots in veins and lungs. hemorrhage, allergic reactions, and even death. I (we) also realize that the following risks and hazards may occur in connection with this particular procedure: I (we) understand that anesthesia involves additional risks and hazards but I (we) request the use of anesthetics for the relief and protection from pain during the planned and additional procedures. I (we) realize the anesthesia may have to be changed, possibly without explanation to me (us). I (we) understand that certain complications may result from the use of any anesthetic including respiratory problems, drug reaction, paralysis, brain damage, or even death. Other risks and hazards which may result from the use of general anesthetics range from minor discomfort to injury to vocal cords, teeth, or eyes. I (we) understand that other risks and hazards resulting from spinal or epidural anesthetics include headache and chronic pain. I (we) have been given an opportunity to ask questions about my condition, alternative forms of anesthesia and treatment, risks of nontreatment, the procedures to be used, and the risks and hazards involved, and I (we) believe that I (we) have sufficient information to give this informed consent. I (we) certify this form has been fully explained to me (us), that I (we) have read it or have had it read to me (us), that the blank spaces have been filled in, and that I (we) understand

Also, Michigan mandates that all women receive a state-approved booklet before mastectomy for breast cancer.

Physicians should be aware of the law in their respective states, both legislative and judicial. Physicians often have many resources available on consent issues, such as state and specialty medical societies. Additionally, liability insurers will often furnish guidance to their insured physicians on consent issues and may have available model consent forms.

In cases in which a legally mandated consent form is not required, a general consent form that identifies the patient, the procedure, the indications, and the risks can be used to document the physician's disclosures and discussion with the patient, and the patient's consent (Fig. B-2). Some states may require a witness to sign the consent form. Many physicians in office practices may ask nurses or other office staff to witness. Because of potential conflict-of-interest issues that may be raised in litigation, physicians may consider having a family member or friend of the patient also witness the consent process, in addition to the physician's staff, if possible.

Patient Consent Form			
I came to the office of Dr. evaluation and treatment of the fol			
(description of diagnosis, etiology, and different diagnosis)			
We discussed the different treatments possible, and discussed the risks of not treating the condition. Based on the advice given by Dr and my own judgment, I agree to undergo the following procedure:			
(description of anesthetic, procedure, and dressing)			
We discussed the different outcomes that could occur, and most of the possible complications. I am aware that other complications could occur that we could not foresee. I agree to follow the instructions for self-care after the procedure, and to return for follow-up care on:

#### MODELS OF MEDICAL DECISION MAKING

The courts have been criticized for setting standards that do not actually reflect medical practice and may interfere with the doctor-patient relationship. The problem may lie in the implementation, not in the actual concept. The ethical concept of informed consent includes the legal concept of consent, but it goes further: the patient must be a partner in the decision-making process (Box B-1). Just as the laws have evolved in clarifying informed consent, the transition toward involving the patient more in the process has also changed.

There are essentially four models of medical decision making:

- Traditional model: The physician decides whether to perform a
  procedure and which procedure to perform; the patient's trust and
  confidence in the doctor replace the need for consent.
- Traditional informed consent: The physician decides whether to perform a procedure and which procedure to perform with the patient's informed consent.
- 3. *Collaboration*: The physician and the patient work together to make a joint decision about the procedure.
- 4. Patient choice: The patient decides with the physician's counsel.

If given a choice, some patients will choose the traditional model, and a few will choose the fourth model. Most patients and physicians are more comfortable with either traditional informed consent or collaboration, and physicians should learn how to use both of these models as well as how to determine which model to use for a specific patient.

Notwithstanding the model of medical decision making utilized, a physician will be held, for liability purposes, to the standard of informed consent adopted by the jurisdiction in which he or she practices. This means that for liability purposes, the physician must ensure that the necessary disclosures to the patient have been made and documented in the medical record and in any consent form used.

#### Box B-1. Elements of Informed Consent

- Disclosure of information
- Competency (the patient is not a minor, unconscious, intoxicated, or incapable of participating in the process)
- Understanding
- Voluntarism
- Decision making
- Patient participation

#### **CONSENT IS A PROCESS**

With the possible exception of treatment needed in emergencies, there is rarely an exception to the rule that all procedures or other treatment—whether office or facility based—should be preceded by disclosure of the material risks and benefits and discussion that allows the patient to participate in and to decide whether to have the procedure or other treatment. In many instances, it may be permissible to obtain and to rely on the patient's oral consent, which should be documented explicitly by the physician in the medical record summarizing all the essential points (risks, benefits, possible complications, alternatives, etc.). In other instances, particularly those involving surgical procedures, the patient should sign a consent form that documents the process utilized. Some states have laws that specify certain language on consent forms for certain procedures.

The process of discussing the procedure with the patient or guardian and providing education about the procedure itself, the possible complications, and aftercare responsibilities of the patient should all be considered part of the consent process. The consent form can be used as a patient education tool, with a copy containing the patient's signature to be given to the patient for reference. Patients can be educated during the consent process about the legal requirements for the signed form and the fact that results of medical procedures are not guaranteed. However, bringing the form out at the last minute for signature can produce some patient anxiety and suspicion. A better approach may be to start the process by giving the patient the consent form to read, then using the form to guide the discussion. For certain procedures, such as vasectomy, the form can be sent out before the consultation visit or given at the time of the consultation. The patient can read it, think about it, then return it before surgery. The consent form can include postprocedure instructions as well as instructions for contacting the physician or an associate if complications occur after hours.

Many liability insurance companies advise that patients view videotapes discussing the proposed procedure. This ensures that the patient has an opportunity to consider all the pertinent information and serves as a record for defense of a lawsuit. However, a videotape is not a substitute for discussion between physician and patient.

The process of informed consent can be summarized as follows:

- 1. Establish responsibility:
  - The doctor's role
  - The patient's role
- 2. Establish expected duration of responsibility.
- 3. Define the problem with the patient.
- Set goals for treatment and establish whether cure is a reasonable expectation.
- Select an approach to treatment; during this step the informed consent form is signed.
- 6. Perform extended treatment and follow-up.

## COMPLICATIONS HAPPEN AND THE CONSENT PROCESS WILL BE SCRUTINIZED

Surgical and other complications are at the core of many malpractice suits. Physicians should not rely solely on a signed consent form for protection in a malpractice suit. Rather, they should rely on the process that resulted in the patient's consent, including the patient's participation in that process. In malpractice litigation, that process will be viewed through the lens of hindsight. A physician who brings out a highly technical consent form to be signed by the patient at the last minute is not likely to be viewed favorably. By itself, such a form may not necessarily be evidence that the patient's consent was informed. A consent form is only one piece of evidence, and in lawsuits other evidence, such as the patient's testimony, is examined as well. A consent form itself cannot—and is not intended to—substitute for a candid discussion with the patient about the procedure and the

inclusion of the patient in the decision-making process, or for documentation in the medical record of the discussion before the patient signs the form. For some patients, particularly uninformed or anxious patients, knowledge of the risk may dissuade them from undergoing an otherwise needed procedure.

Many consent forms use language that is too technical; the forms are often too long to read and interpret during an office visit. Consent forms are often handed to patients during hospital registration by nonprofessional personnel, and some patients are unable to comprehend the procedure even after explanation. The consent form should be meaningful to the patient. Likewise, in order to provide the additional type of documentation that is also useful in a court case, the physician should include in the patient's chart a narrative of the discussion between doctor and patient during the decision-making process, in addition to the actual consent form.

Clinicians should always be careful not to "overpromise" what a procedure can do. Honesty is best. "Never say never and never say always!" There are always exceptions. If someone asks about a rare complication, the clinician should not say it won't happen! It could. An example should be given instead. If the patient plays the lotto, the clinician should ask if he or she is likely to win. The answer is usually "No." But could the patient win? Is it possible? The answer is usually "Yes." So it goes with complications. Will it happen? "Most likely not. But, in rare instances, it could."

It goes without saying that no consent form will protect a physician from true malpractice. Competence and keeping up to date educationally are essential. Seeking expert advice and second opinions is encouraged, and knowing one's limits is essential. Especially in primary care, clinicians must be sure to inform the patient of their training and background; they should not pretend to be an orthopedist, or obstetrician, or plastic surgeon. The patient should seek another opinion if he or she is at all uncomfortable.

As many have said before, the best way to minimize the risk of a lawsuit is to have an excellent physician-patient relationship with both the patient and the family. Each patient is different. Some have a lot of questions that need to be addressed and answered. Some have been let down by the medical system in the past and are fearful. Some have extreme anxiety and no amount of reassurance helps them. Some want absolute assurances that are impossible.

Ultimately, it is the patient's decision whether to accept or reject treatment. As a matter of practicality, sometimes personalities just aren't compatible. When "the vibes are bad" between the patient and the caretaker, clinicians should learn to sense this and not try to "force" things. Providers should recognize that they can't always be all things to all people and that referring a patient to "other experts" is often best for the relationship and to reduce liability exposure.

Complications occur, even though the physician has furnished good quality care with technical perfection. Unfortunately, mistakes can and do happen. Physicians are typically advised by their hospitals, insurers, and legal counsel—and maybe are ordered by their employers—to refrain from expressing sympathy or compassion to the patient or family in these circumstances. The reason is that such statements can be construed as an admission of malpractice and used as evidence against the physician in litigation. Expressions of sympathy also have been seen as inviting malpractice suits. Nevertheless, some institutions have enacted policies of transparency and accountability by admitting errors and volunteering fair settlements. Anecdotal reports suggest that this practice may reduce the number of malpractice suits, the dollar amount of settlements, and defense costs, although there is some debate as to whether the quantity of claims is affected. Approximately 35 states have enacted lawsreferred to as "I'm sorry" laws-which provide that expressions of sympathy and compassion by physicians are inadmissible as an admission of liability in malpractice litigation. The scope of these laws varies among jurisdictions, but typically are narrowly drawn and normally will not shield statements that admit—or can be construed as admitting—fault. Consequently, physicians, when caught up in

the moment, could unwittingly express sympathy or compassion in such a way as to unfairly implicate himself or herself before a jury.

#### **BILLING ISSUES**

Evaluation and management codes are used to bill for surgical consultation, evaluation, and management services furnished by a physician in the office. The informed consent process is included in the evaluation and management codes and is not a separately reimbursable service. The range of available evaluation and management codes varies according to the degree of the examination performed, the history taken, the complexity of the medical decision making, and the time spent with the patient and family. When extended counseling with the patient or family is necessary, the physician should consult with his or her billing advisor to ensure that the appropriate evaluation and management codes are reimbursable and billed.

## LATEX ALLERGY GUIDELINES

Sumana Reddy

Sensitivity to natural rubber latex (NRL) has gained increasing prominence over the last three decades. Latex is now likely the second most important cause of intraoperative anaphylaxis, behind muscle relaxants. Although NRL has been in widespread use for over a century, multiple factors, including a dramatic increase in use and changes in production time and production quality, have led to now well-established reports of severe reactions. In 1997, the National Institute for Occupational Safety and Health (NIOSH) issued an advisory recommending that latex gloves be used only by those workers exposed to blood or body fluids, and not by food handlers, hobbyists, and those performing many housekeeping activities. NIOSH also recommends that if NRL gloves are to be used, they should be low protein and powder free. Increasingly, hospitals are making the decision to be latex-free in terms of glove purchases. It is a reasonable decision, given the prevalence of latex allergy, to do all procedures with nonlatex gloves. Although there are a variety of alternatives to latex, not all have the tensile strength, flexibility, and impermeability of NRL. The solution may be to use different glove materials for examination versus surgery and procedural use.

#### SYMPTOMS OF LATEX ALLERGY

Reactions to NRL are type I, immediate hypersensitivity reactions. They can cause local or systemic urticaria, symptoms of rhinoconjunctivitis or bronchospasm, and anaphylaxis. The proteins of NRL have been described as unique in that an unpredictable course may occur in the progression from no or mild symptoms to anaphylaxis. The sensitization begins and is perpetuated both as a contact allergen and as an inhalant. The greatest degree of sensitization occurs in areas where powdered latex gloves with a high NRL protein content are used. In these situations, the cornstarch powder particles appear to adsorb latex to the surface. These latex-cornstarch powder particles have been demonstrated to aerosolize, especially when gloves are removed. Prolonged exposure through the lungs appears to cause high rates of sensitization. Those who are sensitized may cross-react to certain foods such as banana, kiwi, chestnut, or avocado. NRL gloves may also cause an irritant contact dermatitis from occlusion and frequent handwashing, or a delayed hypersensitivity reaction from chemicals used in processing. These are not reactions to latex itself (Box C-1).

#### **RISK GROUPS**

Those at greatest risk of sensitization are all those groups with cumulatively prolonged exposure to latex. The greatest prevalence appears to be in those who have undergone repeated surgeries, especially children with spina bifida or urogenital abnormalities. Others at risk include workers in the latex manufacturing industry and health care workers. Studies indicate 10% to 17% of health care workers have already become sensitized, and over 2% have occupational asthma as a result of latex exposure. In addition, over 50% of persons who are sensitive to latex have a history of atopic illness, or hay fever (Box C-2).

#### **NONLATEX MATERIALS**

The establishment of universal precautions in 1985 has led to an increased use of latex gloves through the spectrum of health services from phlebotomy to nursing home care. This use is now being reevaluated in light of our growing understanding of the process of sensitization. As recommended by NIOSH, all health care providers should make purchasing decisions avoiding the use of powdered, high-protein latex gloves, in favor of powder-free, low-protein gloves. Where possible, nonlatex gloves should be used. As mentioned, in the last decade this has become an increasingly popular solution. These measures have led to a probable drop in the incidence of latex allergy, and certainly a deceleration in the rate of newly sensitized individuals.

There is a range of surgical and nonsurgical gloves available in nonlatex materials. These have been ASTM (American Society for Testing and Materials) tested for barrier integrity and are expected to provide protection against viral particles such as human immunodeficiency virus (HIV) when used as recommended. Vinyl gloves are not as effective as other materials against viral penetration.

## Box C-1. Symptoms and Signs Associated with Latex Glove Use

#### Irritant Contact Dermatitis (Nonimmune)

Gradual onset, over days, caused by handwashing, occlusion, antiseptics, and glove chemicals

Redness

Cracks, fissures

Scaling

## Allergic Contact Dermatitis, or Type IV (Delayed Hypersensitivity)

Onset 6 to 48 hours after contact, caused by chemicals

Erythema

Vésicles

Papules

Pruritus

Blisters

Crusting

#### Immediate Hypersensitivity, or Type I

Local and generalized urticaria onset within minutes, very rarely longer than 2 hours; caused by latex

Feeling of faintness

Feeling of impending doom

Angioedema

Nausea, vomiting, abdominal cramps

Rhinoconjunctivitis

Bronchospasm

Anaphylactic shock

#### Box C-2. Risk Groups for Latex Allergy

Occupational latex exposure

Health care workers

Rubber industry workers

Medical patient exposure

Spina bifida

Urogenital abnormalities

Other repeated or prolonged surgeries or mucous membrane exposure to latex devices, especially early in life

Atopic history or food allergy (especially bananas, avocados, kiwis, and chestnuts) (cross-reacting protein epitopes)
Low risk: no identifiable risk factors

#### **DIAGNOSIS**

In performing procedures, there are issues of identifying the patient who may be latex allergic, and avoiding exposure through inadvertent use of a product containing latex. Use of a standardized questionnaire is recommended where any suspicion may exist (Box C-3). It is also important to prevent the development of latex sensitization in the health care workers performing and assisting in the procedure. The use of nonlatex gloves and supplies can streamline processes, and has become more of an option as these gloves become competitively priced.

The diagnosis of latex sensitivity is not straightforward. It is made through a combination of thorough medical history and immunologic testing. Because symptoms can be generalized and nonspecific, the sensitized individual often remains unaware of the condition. Standardized extracts for prick testing are not available

## Box C-3. Screening Questionnaire for Latex Sensitivity

#### I. Allergies

- Have you had a history of hay fever, asthma, eczema, allergies, or problems with rashes?
- Are you allergic (rash, oral itching, swelling, or wheezing) to any foods, especially bananas, avocados, kiwi, or chestnuts?

#### II. Job-Related Symptoms

- Does your work involve any exposure to latex products, including latex gloves? Have you ever had allergic reactions to something in your work environment?
- If you have had a rash on your hands after wearing latex gloves, how long after putting on the gloves did the rash develop? What did it look like?

#### III. Hidden Reactions to Latex

- Have you ever had swelling, itching, hives, shortness of breath, cough, or other allergic symptoms during or after blowing up a balloon, undergoing a dental procedure, using condoms or diaphragms, or following a vaginal or rectal examination?
- Have you ever had an allergic reaction of unknown cause, especially during a medical or dental procedure?

#### IV. Surgical History

- Have you ever had surgery, and if so, what type?
- Do you have spina bifida or any urinary tract problem requiring surgery or catheterization?

in the United States. Therefore, such skin testing should be carried out only by centers with experience in preparing extracts and may cause a high incidence of anaphylaxis. Food and Drug Administration (FDA)—approved in vitro tests to measure latex-specific IgE are available (Pharmacia CAP, Pharmacia-UpJohn Diagnostics Inc.; AIaSTAT, Diagnostic Products Corp.; and HYTEC, HYCOR Biomedical). The low specificity of these tests, with at least 20% false-negative results and unclear positive predictive value, gives them limitations. Negative serologic testing with a strongly positive history would suggest the value of skin prick testing in experienced hands to confirm the diagnosis. Because individuals with no risk factors or prior symptoms have had anaphylactic reactions, those who are asymptomatic with positive tests should be advised to exercise caution.

If in doubt at the time of performing a procedure, it is best to avoid use of latex-containing medical devices and products. Especially prone to cause reactions are gloves and urinary catheters placed in direct contact with mucosal surfaces (e.g., during pelvic examinations).

The task of identifying latex-containing medical devices has been simplified by FDA requirements indicating on packaging whether latex is contained in a product. Lists of latex-containing

#### Box C-4. Sources of Possible Latex Exposure

#### Medical Devices with Potential Latex Content

Adhesive tape

Ambu-bags

Bandages

Bulb syringes

Dental devices

Electrode pads

Face masks

Gloves

Injection ports

Mattresses on stretchers

PCA syringes

Rubber syringe stoppers and medication vial stoppers

Stethoscope and BP cuff tubing

Tourniquets

Urinary catheters

Wound drains

#### Household Items with Potential Latex Content

Balloons

Buttons on electronic equipment

Carpet backing

Clothing, including elastic on underwear

Computer mouse pads

Condoms and diaphragms

Diapers

Erasers

Feeding nipples and pacifiers

Food handled with powdered latex gloves

Handles on racquets, tools

Many toys

Rubber bands

Sanitary and incontinence pads

Shoe soles

Sports equipment

BP, blood pressure; PCA, patient-controlled analgesia. A more detailed and periodically updated list of latex-containing products and nonlatex substitutes by brand name is available from the Spina Bifida Association of America (1-800-621-3141 or http://www.sbaa.org).

## Box C-5. Latex Allergy Management Guidelines for the Hospital Setting

- Ask all patients about latex sensitivity, using a screening questionnaire if relevant.
- Place latex allergy identification bracelet on patient in admitting area.
- Label room as latex-safe and enter in all relevant areas of signage, notes, and databases.
- Disseminate latex allergy protocol and lists of nonlatex substitutes for latex-containing materials that may contact the patient.
- Remove all latex products that would contact the patient and remove all latex gloves. Use PVC tubing or wrap cotton gauze over the extremity if using latex cuffs and tubing or tourniquets.
- Ensure that adhesives and tapes, including ECG electrodes and dressing supplies, are checked for latex content.
- Have a latex-free crash cart available to follow the patient through his or her stay.
- Notify Pharmacy and Central Supply that the patient is latex-sensitive so that latex contact can be eliminated in preparation of materials or drugs for the patient.
- Notify Dietary of relevant food allergies and avoid handling food with powdered latex gloves (NIOSH recommended and mandated by many states).

ECG, electrocardiogram; NIOSH, National Institute of Occupational Safety and Health; PVC, polyvinyl chloride.

and latex-free devices may be obtained both directly from individual manufacturers and from the Spina Bifida Association of America. As Box C-4 shows, many medical and household items contain latex. To a sensitized person, all of these may be problematic. To an unsensitized person, the thin stretchy rubber of gloves, condoms, and balloons provides the greatest source of rubber particles leaching from the surface. Solid, molded rubber objects are less likely to leach proteins from their surfaces.

#### **MANAGEMENT**

A history of type 1 immediate hypersensitivity reactions necessitates a latex-safe environment. Patient records should be identified clearly for latex allergy, and at no time in treatment should latex gloves, tourniquets, catheters, or other materials come in direct contact with the patient. If blood pressure cuffs and tubing are made of latex, the patient's extremities should be wrapped to prevent contact. Although rubber medication vial and syringe stoppers are listed, to date there have been only rare reactions to medication in contact with latex. For the most part, then, extreme measures (e.g., only using medication from glass ampules or glass syringes) are not recommended. The hospital guidelines provided may be adapted as applicable for an outpatient setting (Box C-5).

Premedication with antihistamines or steroids is not helpful. It may only mask symptoms leading to anaphylaxis without preventing anaphylactic reactions. Persons with latex hypersensitivity should carry an epinephrine autoinjection kit and wear MedicAlert identification. In the medical office it is always advisable to have available sterile nonlatex gloves for use.

#### **SUPPLIERS**

See Table C-1 for a list of suppliers of hypoallergenic nonlatex gloves.

#### **CONCLUSION**

For those who have been sensitized, avoidance is the cornerstone of management. In all settings where gloves are heavily used, avoiding sensitization through purchase of powder-free gloves is recommended. Almost all hospitals have gone toward powder-free and low-protein gloves, and increasing numbers are opting to convert to entirely nonlatex products. This choice has already begun to have a positive impact on the patient with latex allergy and to prevent sensitization in the health care worker. Ironically, with this condition, it is the health care worker who is often the patient.

# RESOURCES FOR LEARNING AND TEACHING PROCEDURES

Stephen J. Wetmore • Steven E. Roskos

The well-rounded primary care physician performs a variety of medical and surgical procedures in his or her practice. The skill in performing such procedures and resultant success will depend strongly on the training that one has received in performing those procedures. Advancing technology and changing practice patterns lead primary care physicians to add new procedures to their practices and to update their skills in procedures that they already perform. Regardless of whether the clinician is learning a procedure for the first time or wishing to update skills, it is helpful to have a good understanding of the resources that are available to facilitate learning.

This appendix provides information about the variety of resources available for learning procedures and how these can be accessed. A new section in this appendix includes some tips for teaching and learning procedures in family medicine. This is also of considerable interest to teachers of procedural skills. It is not possible to include every resource, but each section will have examples and provide ideas about where to search for other similar resources.

# COURSES IN PROCEDURES FOR PRIMARY CARE PHYSICIANS

In both Canada and the United States, national medical associations such as the College of Family Physicians of Canada and the American Academy of Family Physicians provide opportunities to learn and update procedure skills. National and state or provincial meetings of these bodies often have seminars or workshops on common procedures in primary care. Seminars and workshops are excellent starting points for physicians hoping to learn procedures because they will include the pertinent background knowledge for each procedure, including indications, contraindications, technical details, and complications. Many of these workshops also include opportunities for "hands-on" experience, which allows physicians to become familiar with equipment and techniques. These sessions are suitable as updates for physicians already familiar with the procedures but often do not provide enough practical experience in some procedures for new learners to commence performing them right away. They are, nevertheless, good starting points.

The National Procedures Institute (Texas) is a joint venture of The Texas Academy of Family Physicians, The American Academy of Family Physicians, and The Society of Teachers of Family Medicine. A variety of courses in procedure skills can be found on its website (www.npinstitute.com). The range of procedures covered in these courses is extensive, and readers are referred to the course outlines on the website for details.

The following are examples of nationally recognized programs with standards and hands-on practical training that must be met to receive credit:

Advanced Cardiac Life Support (ACLS)
Advanced Life Support in Obstetrics (ALSO)
Advanced Trauma Life Support (ATLS)
American College of Sports Medicine (www.acsm.org)
Basic Life Support (BLS)
Canadian Academy of Sports Medicine (www.casm-acsm.org)
MOREOB program (http://moreob.com)
Neonatal Resuscitation Program (NRP)
Pediatric Advanced Life Support (PALS) (www.americanheart.org)

# **TEACHING PROCEDURES**

Physicians find themselves teaching procedures in various settings, both formal and informal. You may give a workshop to family medicine residents on a certain procedure. You may teach a procedure to a medical student spending time in your office. The principles of effective instruction remain the same, though their application to these different situations may vary.

Which procedures should be taught and learned? Each practice situation will require different procedural skills, so no list will be universal. Some good starting points include the core list of procedures for family physicians developed by the Working Group on Procedure Skills of the College of Family Physicians of Canada or the list of core procedures for family medicine developed by the Society of Teachers of Family Medicine (STFM) Group on Hospital Medicine and Procedural Training.

Several other papers in the medical literature provide valuable information about procedure skills training in American and Canadian family medicine training programs. What should the content of teaching and learning procedures include? Although the first component that comes to mind is the technical skill, there is much more to learn about a medical procedure. The Working Group on the Certification Process of the College of Family Physicians of Canada has defined the key features that must be included for each procedure. These features are discussed in the following section.

# **KEY FEATURES OF PROCEDURAL SKILLS**

- 1. In order to decide whether or not you are going to perform a procedure, consider the following:
  - The indications and contraindications to the procedure
  - Your own skills and readiness to do the procedure (e.g., your level of fatigue and any personal distracters)
  - The context of the procedure, including the patient involved, the complexity of the task, the time needed, the need for assistance, and location.

- 2. Before deciding to go ahead with the procedure, consider the following:
  - Discuss the procedure with the patient, including a description of the procedure and possible outcomes, both positive and negative, as part of obtaining consent.
  - Prepare for the procedure by ensuring appropriate equipment is ready.
  - Mentally rehearse the following:
    - The anatomic landmarks necessary to perform the procedure The technical steps necessary in sequential fashion, including any preliminary examination

The potential complications and their management

- 4. During performance of the procedure
  - Keep the patient informed to reduce anxiety.
  - Ensure patient comfort and safety always.
- 5. When the procedure is not going as expected, stop, reevaluate the situation, and seek assistance as required.
- 6. Develop a plan with your patient for aftercare and follow-up after completion of a procedure.

Good working understanding of these key features is prerequisite to performing any procedure and needs to be taught and learned in addition to the technical skill itself. The goal of teaching a procedure is that the learner be able to perform the procedure in the real world on a real patient. When teaching medical procedures, it is best to treat them as a relatively "closed" skill, in other words, with specific steps that the learner should not deviate from. Once the procedure is mastered, variations can be introduced to address different anatomy or other variations in the clinical situation.

The OOMPA ED WASDM PF SIOMT acronym explained in the following sections can help you remember to incorporate all the steps to effective instruction.

#### Introduction

- O—Objective. To perform a given procedure on real patients in the real world.
- O—Overview. Provide a quick summary of the steps involved.
- M—Motivation. Why should the learner gain proficiency in this procedure? Provide information on how often this procedure is required, what the benefits are, and the consequences of not acquiring skill in this procedure.
- P—Prerequisites. Before learning the technical skills required to perform a procedure, the learner needs to know the indications, risks, anatomy, and so forth. This is a good opportunity to refer the learner to a chapter in this text. The best way to assure that the learner knows the prerequisite information is to ask questions: "What are the indications for this procedure?" "What are the risks?" "What complications would you keep your eye out for?" Role playing works as well: "Pretend I am the patient and obtain informed consent for this procedure from me." Pictures and models are also very helpful in cementing this information in the learner's mind.
- A—Agenda. Describe what the learner can expect. If you are giving a formal lesson or workshop, describe what it will contain. If this is informal teaching in the office, explain that you will list and explain the steps, demonstrate them in some way, and ask the learner to demonstrate them as well.

# **Core Material**

ED—Explanation and demonstration. This portion of the instruction is key. Even if the learner has performed this procedure several times, it is helpful to review the steps and then have the learner repeat them, and even have the learner demonstrate the procedure in some way before beginning the actual procedure on a patient.

The explanation and demonstration phase can be outlined by the WASDM acronym:

W—"You will perform this procedure."

A—"Attend to these steps as I show you how to do them."

SD—Say each step before doing it.

M—Ask the learner to memorize the steps and recall them before the practice.

Sometimes dividing the procedure into discrete steps can be difficult and it is easy to leave a step out. Use this text as a starting point to list all the steps for a procedure. If the instruction is for a formal setting, ask others who are familiar with the procedure to review the steps. Then, ask someone who is unfamiliar with the procedure, perhaps someone who is nonmedical, to try to learn the procedure using this method. This person can often point out missing steps or incomplete instruction. If the situation is informal, add steps as you go if you realize that you have left some out. When teaching complex procedures, it may be best to divide them into segments, and teach the segments separately, combining them later. For example, when teaching laceration repair, local anesthesia may be separated from suturing.

You may demonstrate a procedure in several ways. The best way is on a real patient. However, if you want the learner to perform a procedure on that patient, the patient probably doesn't need two procedures. On the other hand, if the patient needs both knees injected or two moles removed, this is the perfect opportunity to demonstrate and then have the learner perform the procedure, a classic case of "see one, do one." If several procedures are being performed in succession, for example, several colonoscopies are scheduled in the endoscopy laboratory, you can demonstrate on the first one and let the learner try the second one. It is very important to follow the WASDM acronym when demonstrating so that the learner gains maximum benefit from the demonstration.

If a real patient is unavailable for demonstration, mock demonstration using capped needles or covered scalpels is useful. Video demonstration is an excellent alternative and there are many resources available for video demonstration (see Table E-2).

PF—Following demonstration, practice with feedback is very important. The learner can practice on a real or simulated patient. The learner should state the steps as they do them ("say, then do"). It is important that the practice be in an environment that is encouraging and pleasant. If there really isn't time to teach the procedure, it is better to wait for another opportunity. A stressful and high-pressure setting is not conducive to learning and may discourage the learner from future attempts at learning a procedure. Do your best to be encouraging and positive during the practice. If the learner is forgetting a step or not performing it properly, ask them to stop and think "What step are you missing?" or "That's not quite right. How should you perform this step?" Specific feedback is very important. Rather than saying "good job," try pointing out specific things that were done well, for example, "you really kept that site sterile throughout the procedure" or "your conversation with the patient put him at ease."

# Conclusion

Whether in a formal or informal instructional situation, it is important to review and summarize (SIOMT):

- S—Summary. Review the steps.
- I—Integration. Explain how this procedure might fit in with other treatments for the same condition or other procedures that are related.
- O—Objective. Review the objective (to perform the procedure on a real patient in the real world).
- M—Motivation. Review the motivation.
- T—Test. If you need to assess competency, have the learner perform the procedure while you observe. The best situation is performing

the procedure on a real patient. If this is not possible, then performing the procedure in some simulated fashion may suffice.

Teaching procedures is challenging and rewarding. Seeing a learner achieve competence and independence in performing procedures is one of the greatest rewards of the physician–educator. Following these tips can help you do so effectively and efficiently.

# GAINING PRACTICAL EXPERIENCE IN PROCEDURES

Although formal courses or workshops are suitable for learning information about procedures, equipment, and techniques, it may not be possible for the clinician to gain enough experience in this way to begin performing the procedure. Supervised practice is necessary to gain confidence in many procedures. In most cases there is no consensus on how many supervised procedures are necessary to achieve competence. The number of supervised procedures necessary to achieve competence for any given procedure depends on the complexity of the procedure, and the confidence and physical dexterity of the operator, among other things. For example, a learner may need to perform 25 to 30 supervised flexible sigmoidoscopies to achieve competence but only 10 to 15 supervised no-scalpel vasectomies. Clinicians should consider performing procedures under the supervision of an experienced colleague until both are comfortable with the learner's competence. Supportive colleagues can be a major resource toward getting started in procedures and providing backup and support when difficulties arise.

# **BOOKS ON PROCEDURES IN PRIMARY CARE**

With the rise in technology and increasing use of CD-ROMs, computer animations, and virtual reality, there is less emphasis on books for many of the things we do in practice. Nevertheless, textbooks remain a readily available source of practical information. One or two texts on procedural skills are an essential part of the primary care physician's library. This book, Pfenninger and Fowler's Procedures for Primary Care, 3rd ed., is one example of an ideal resource book because of its comprehensive nature, inclusion of background material, patient education, description of technique, helpful illustrations, company names and addresses for obtaining equipment, and billing and coding information. Many common primary care procedures are covered in The Essential Guide to Primary Care Procedures, by E.J. Mayeaux, Jr. (2009), and there is access to a companion website with patient education handouts and videos (Lippincott Williams & Wilkins). Another excellent resource for dermatology procedures is Habif's Clinical Dermatology: A Color Guide to Diagnosis and Therapy, 4th ed. (WB Saunders, 2004) and its associated website www.clinderm.com. Usatine's text Dermatologic and Cosmetic Procedures in Office Practice (Elsevier, 2011) is a comprehensive review of dermatologic procedures.

The following are examples of other important texts; they are but a few of the "must have" texts for any library:

Apgar's Colposcopy: Principles and Practice, 2nd ed. (Saunders, 2008) Diagnosis and Office Orthopedics for Primary Care, by B.C. Anderson (WB Saunders, 2006)

Emergency Medicine Procedures, by E.F. Reichman and R.R. Simon (McGraw-Hill, 2004)

Essentials of Musculoskeletal Care, 3rd ed., by L.Y. Griffin, comes with a DVD (American Academy of Orthopedic Surgeons, 2005)

Essential Orthopedics, by M. Miller (Elsevier, 2009), comes with a DVD (videos on how to perform 29 joint injections, 7 common physical examinations, and 6 splinting and casting procedures) and full-text online access

A Practical Guide to Joint and Soft Tissue Injection and Aspiration: An Illustrated Text for Primary Care Providers, by James W. McNabb (Lippincott Williams & Wilkins, 2009)

Surgery of the Skin, by J.K. Robinson, et al. (Mosby, 2005)

A more complete list of other available texts can be found in Table E-1.

# CD-ROM/DVD RESOURCES FOR PROCEDURES IN PRIMARY CARE

CD-ROMs and DVDs are useful resources for learning procedures because the technology allows the integration of text with voice, pictures, computer animation, and videotape. These can be searched easily to focus on specific details of any given procedure. Like textbooks, CD-ROMs can provide all the relevant background information necessary to perform the procedure. Texts now often contain a DVD and online access (see Miller's Essential Orthopedics, cited previously). One strength of this technology is the capacity to incorporate video footage; the visual presentation of the technique is a powerful learning aid. CD-ROMs are portable and can be used in a variety of settings, including the office, clinic, or even the home. As an example is a DVD, Multimedia Primary Care Procedures by Tuggy, Garcia, and Newkirk. The quality of the DVD and visualization of the techniques are excellent. This DVD includes patient guides, voice or text instruction for each procedure, and access to ICD-9/CPT codes for each procedure. The purchase of Multimedia Primary Care Procedures also provides access to the website (www.primarycareprocedures.com), which is regularly updated, and video footage of additional procedures is available. This works well for teaching many students and residents in a lecture format as well as small groups. Box E-1. lists the contents of this DVD.

Deutchman has produced two excellent DVDs: Emergency and Trauma Ultrasound and Cesarean Delivery. Links to these products can be found at http://www.chall.com/emus.htm and http://www.chall.com/cesarean.htm, respectively. Descriptions and contents can be found in Box E-2.

The National Procedures Institute produces a series of learning DVDs that are listed in Box E-3.

MeisterMed recently launched its *Procedures: Hospital Collection* for iPhone and iPod touch (www.meistermed.com/procedures). It includes videos, images, and step-by-step details for 15 key inpatient procedures.

The American College of Physicians-American Society of Internal Medicine has two products: Arthrocentesis and Joint Injection (Alguire PC, Casey LM, eds., 1999) and Common Skin Biopsy Techniques (Alquire PC, Casey LM, eds., 1999) that include videotapes of the procedures.

#### **WEBSITES**

First Consult (www.firstconsult.com) is an informative website that is constantly being updated. Many procedural topics are outlined and each includes a short video clip of the procedure as well the indications, contraindications, techniques, outcomes, and resources. Subscription is required but the value of the resource is worth it.

Another good resource for teaching is The Family Medicine Digital Resources Library (FMDRL), produced by the Society of Teachers in Family Medicine (STFM), available at www.fmdrl.org. This website contains user-posted conference presentations and handouts, and shared curricular materials such as PowerPoint lectures, learning modules, syllabi, digital images, video and audio recordings, and recommended websites. All of the content has been peer reviewed and anyone can search the database and download materials. Registration is required but free if you want to upload material to share with others. One example is a PowerPoint presentation entitled "Procedure World: A New Paradigm for Teaching Procedural Skills" by Ellen Johnson which illustrates one teaching program for procedural skills.

The American Academy of Family Physicians website now includes a self-study program on clinical procedures designed for physicians to review and build confidence in procedural skills. Most of the programs (e.g., Joint Injection and Aspiration, No Scalpel

# Box E-1. Procedures Included in Multimedia Primary Care Procedures

Abdominal paracentesis

Amniotomy Anoscopy

Arthrocentesis—knee aspiration Banding of internal hemorrhoids Barrier contraceptives (diaphragm) Bartholin's gland—marsupialization

Bartholin's gland—Word catheter placement

Bladder catheterization—female Bladder catheterization—male Burn débridement

Cerumen impaction removal Cervical polyp removal

Cervical sampling (wet smear with KOH preparation)

Cesarean section Colposcopy

Complete nail removal

Curettage and cautery—basal cell carcinoma

Digital block
Endometrial biopsy
Enisistemy lacero

Episiotomy—laceration repair Excisional skin biopsy Flexible sigmoidoscopy

Ganglion injection/aspiration Incision and drainage of abscesses

Incision and drainage of thrombosed hemorrhoids

Inverted subcuticular stitches

IUD insertion IUD removal Joint injection—knee Joint injection—shoulder

Lipoma removal

Lipoma removal by extrusion

Local anesthesia

Loop electrosurgical excision procedure (LEEP)

Lumbar puncture Mattress stitches Nasogastric intubation Nasopharyngoscopy Needle aspiration of breast cysts

Neonatal circumcision No-scalpel vasectomy Obstetric ultrasound

Optimal circumcision anesthesia

Pap smear (and wet prep Pap smear with HPV sampling)

Paracervical block

Performing an instrument tie Pilonidal cyst excision Placing an Unna boot Punch biopsy

Radiofrequency mole excision/shave biopsy

Radiofrequency spider vein ablation

Removal of ingrown toenail

Ring removal Scalp cyst excision Shave biopsy Skin tag removal

Subacromial shoulder injection Subclavian line placement Subcuticular running stitches Subrapubic taps or aspirations

Thoracentesis

Thyroid fine needle aspiration Tissue adhesives—use of tissue glues

Topical anesthesia Topical hemostasis Trigger point injection Tubal ligation Vaginal delivery Vulvar biopsy V-Y flap closure

Wart treatment (peripheral and plantar)

HPV, human papillomavirus; KOH, potassium hydroxide; IUD,

intrauterine device; Pap, Papanicolaou.

From www.primarycareprocedures.com (Tuggy M, Garcia J: Procedures Consult. Philadelphia, Elsevier, 2009; also available at www.proceduresconsult.com).

Vasectomy, and Soft Tissue Surgery) include a DVD and syllabus, which can be purchased online by both AAFP members and nonmembers. The website www.proceduresconsult.com is paired with this text. Models are animated in three-dimensional (3-D) imagery.

The site www.primarycareprocedures.com is paired with Tuggy's *Multimedia Primary Care Procedures* (Elsevier) and is accessible when the DVDs are purchased.

Ethicon has several resources online. Not only is there a catalog of sutures, but a full 229-page comprehensive wound closure manual can be found at http://www.pilonidal.org/pdfs/wound closure.pdf.

More and more video clips of procedures and other resources are becoming available on the Internet. A more complete list is found in Table E-2.

# **ARTIFICIAL MODELS AND LEARNING PROCEDURES**

Lack of opportunities for enough practice is a common obstacle to learning procedures in primary care. Models and simulations provide an opportunity to practice skills when patients requiring the procedure are not available. Many physicians who have taken such courses as Advanced Cardiac Life Support (ACLS), Advanced

Trauma Life Support (ATLS), Advanced Life Support in Obstetrics (ALSO), and the Neonatal Resuscitation Program (NRP) can appreciate the value of practicing and learning with models. Similar models are widely used in courses for teaching procedures. Research has shown that artificial models can be effective for learning and retaining technical skills. They can also be helpful in the clinical setting to rehearse a procedure before performing it on a patient. Companies such as Medisim Corp. (www.medisim.ca), Sawbones (www.sawbones.com), 3-Dmed Surgical Training Aids (www. 3-Dmed.com), and Limbs & Things Ltd. (www.limbsandthings.com) offer highly realistic models for learning and practicing medical and surgical procedures. You will find a full listing of available models and costs at their websites.

Figure E-1 shows a realistic pelvic model developed by Medisim Corp. in cooperation with Ontario College of Family Physicians as part of the Benign Uterine Conditions Project. The soft tissue component of this model was developed from a casting of a human model. Its highly realistic features allow for practicing pelvic examination, endometrial biopsy, intrauterine device insertion, and pessary fitting. This model has proved itself in teaching skills to family physicians and family medicine residents as part of the skills transfer workshop associated with the Benign Uterine Conditions Initiative (www.machealth.ca/programs/buc).

# Box E-2. Contents of Deutchman's Emergency and Trauma Ultrasound Examination and Cesarean Delivery DVDs

#### Emergency and Trauma Ultrasound Examination

This CD-ROM-based course is designed to teach the basic technique of emergency ultrasound examination. The course contains a combination of still and video segments as well as diagrams, three-dimensional animation, and interactive multimedia that describe the key concepts of ultrasonography.

Chapters include the following:

Introduction

Physics and orientation

Trauma ultrasound examination

Cardiac examination

Right upper quadrant examination

Abdominal aorta examination

Renal examination

OB/GYN examination

Lower extremity venous examination (DVT)

Sonographic guidance of procedures

20 hours of AMA Category 1 CME credit Link to product: http://www.chall.com/emus.htm

#### Cesarean Delivery

This DVD contains 50+ minutes of high-quality surgical video demonstrating all aspects and multiple variations of cesarean surgical technique and tubal ligation technique, as well as assisting at surgery. Although the procedure must ultimately be taught in the operating room, viewing high-quality DVD video of the standard technique and its variation is helpful both to new learners and to more experienced physicians interested in improving their skills.

These techniques are included:

Patient positioning and preparation

Abdominal incisions: vertical and transverse

Opening the uterus

Delivery of the infant from cephalic and breech

presentations

Use of vacuum extractor

Delivery of the placenta

Closure of the uterus

Tubal ligation technique

Closure of the abdomen and skin

6 hours of AMA Category I CME credit Link to product: http://www.chall.com/emus.htm AMA, American Medical Association; CME, continuing medical education; DVT, deep vein thrombosis; OB/GYN, obstetrics/ gynecology.

Figure E-2 shows the artificial breast model developed by Medisim. The texture and feel of the skin and breast tissue are highly lifelike. With this model a breast cyst can be palpated and aspirated. The cyst will actually disappear when aspirated properly in a very realistic simulation of a clinical situation.

Figure E-3 shows the simulated skin model produced by Limbs & Things Ltd. Once again the skin is very lifelike when handled with instruments. Modifications of this model can be used to practice cyst or lipoma excision in a realistic fashion. The skin simulator can be adapted for different features, as is illustrated in Figure E-4,

which shows how the model can be used to simulate excision of a sebaceous cyst.

Figure E-5 shows the Face with Lesions, produced by Limbs & Things. Some of these lesions can be excised, creating a realistic simulation of skin surgery of the face, where scar orientation, lines of tension, and similar issues have to be considered.

Figure E-6 shows the NPI Down's Cervical Model, which can be biopsied, frozen, and used for performing an endocervical curettage.

Figure E-7 shows the very realistic NPI vasectomy model.

Figure E-8 shows the use of an orange to practice shave biopsy. 3-Dmed Surgical Training Aids provides multiple models and simulators (www.3-Dmed.com). These items include portable endoscopic/laparoscopic trainers, open procedure surgical trainers (episiotomy repair, suturing pads, coordination models, etc.), com-

puter interface equipment, and more.

The cost of commercially available models for practicing procedure skills can be considerable. There is always the possibility of using less expensive, less realistic models for learning procedures. In fact many of these have been developed and described in various articles. Some of the models have been used in studies and shown success in improving a trainee's knowledge and confidence in procedure performance. In Table E-3 a variety of such models is listed. Some are quite traditional; some are very innovative. Nearly all are low cost, easily available, or reproducible. Appropriate references are provided in the table.

# Box E-3. DVDs Available from the National Procedures Institute

The Basics of Cardiac Stress Testing
The Basics of Radiofrequency Surgery
Billing and Coding for Dermatologic Procedures
Common Office Dermatologic Procedures: Patient Cases
Excisions and Common Wound Repairs: Patient Cases
Hospitalist Procedures: Collection 1
Hospitalist Procedures: Collection 2

# COMPUTER SIMULATION AND VIRTUAL REALITY IN LEARNING PROCEDURES

Simulation as a teaching technique has played a significant role in the training of pilots. The advent of virtual reality means that there is now the capability to combine 3-D visual imagery with the ability to interact. This can create very realistic simulations, which are

useful for training surgeons. The use of simulation has been demonstrated for laparoscopic and neurosurgical procedures and will be valuable for such techniques as sigmoidoscopy, colonoscopy, and hysteroscopy, among others. These simulations have proved very valuable for training in the various endoscopic techniques and ultrasound. While much of the attention has been given to invasive or minimally invasive surgical procedures, such devices will be helpful for training in suturing, line placement, biopsy, lumbar puncture, and many other procedures in emergency medicine. It should be pointed out that a systematic review of simulation methods currently used for surgical training has not shown them to be any better

**Figure E-8** Using an orange to practice shave biopsy. (Courtesy of Linda Prine, MD.)

than other forms of training but, as there are such rapid advances in technology being made, there has to be continuous research in this area. In general, the more lifelike the simulations, the better the learning. Issenberg and associates have shown that high-fidelity medical simulations are educationally effective and complement usual medical training. Their value lies in the ability to receive feedback and experience repetitive practice. Application of such sophisticated training to the more common family medicine and emergency medicine procedures would be welcome. Although such virtual simulations are very expensive to develop, they can be reused indefinitely without deterioration and may be available, in part or in total, for long-distance learning over the Internet. There is currently an excellent computer simulator available from Immersion Medical (www.immersion.com) and (www.cae.com/en/healthcare/ surgical.solutions.asp) to teach upper and lower gastrointestinal endoscopy. Although expensive, this unit comes as close to the real-life experience as possible.

Many medical schools now have simulation centers, where models and computer simulations are used to train students and residents. You may wish to contact the nearest medical school to see if they have such a center and if it would be available to you for practice or teaching.

# **PROCEDURE-ORIENTED ASSOCIATIONS**

In addition to the general societies, those interested should be made aware of The American Association for Primary Care Endoscopy (AAPACE, www.aapace.org) and The American Society for Colposcopy and Cervical Pathology (ASCCP, www.asccp.org),

which provide detailed learning in special interest areas. The Society of Teachers of Family Medicine (STFM) Group on Hospital Medicine and Procedural Training is focused on all aspects of teaching procedural skills.

# **CONCLUSION**

In conclusion, the resources available for learning procedures range from courses at medical association meetings, books, CD-ROMs, DVDs, artificial models, and simulations all the way to virtual reality.

Clinicians can learn the background for each procedure, indications, contraindications, complications, and techniques from books, CD-ROMs, and DVDs. However, the ability to practice psychomotor skills is crucial to gaining confidence. Suitable practice can be achieved by using appropriate artificial models, biologic models, and other simulations. Such practice will facilitate learning in the clinical setting and skill maintenance.

Primary care physicians should remember that their primary care colleagues and specialist consultants are valuable resources for learning procedures through their teaching, encouragement, and support during skill learning.

The listing of resources provided in this chapter should be helpful for teachers and learners in developing the skills and the support necessary to provide our patients with quality care in primary care procedures.

# Universal Precautions

Madelyn Pollock

In discussion of universal precautions, it is important to understand the terminology used by the entities that promulgate the guidelines: primarily the Centers for Disease Control and Prevention (CDC) and the Occupational Safety and Health Administration (OSHA). Before 1983, the recommendations of public health agencies in handling blood and body fluids centered on special precautions taken with individuals known or suspected of being infected with bloodborne pathogens. These guidelines were known in the health care industry as "Blood and Body Fluid Precautions." With the increasing prevalence of human immunodeficiency virus (HIV) and hepatitis B virus (HBV) infections and the possibility that these diseases could be undiagnosed in patients, the CDC published "universal precautions" in 1983, recommending that blood and body fluids from all patients be considered potentially infectious and that rigorous infection control precautions be taken to minimize the risk of exposure to health care workers.

In 1996, the CDC modified its recommendations for infection control in the hospital setting, introducing the terminology "standard precautions." To quote the CDC in *Guideline for Isolation Precautions in Hospitals*, "Standard Precautions synthesize the major features of Universal (Blood and Body Fluid) Precautions (designed to reduce the risk of transmission of bloodborne pathogens) and Body Substance Isolation (designed to reduce the risk of transmission of pathogens from moist body substances). Standard Precautions apply to (1) blood; (2) all body fluids, secretions, and excretions except sweat, regardless of whether or not they contain visible blood; (3) nonintact skin; and, (4) mucous membranes."

In 1991, OSHA, a federal agency within the Department of Labor, issued a separate standard. OSHA's Bloodborne Pathogen Standards is based on the concept of universal precautions. It is intended to protect employees who might be exposed to blood or body fluids on the job. (See Online Resources for citation of the complete statute.)

A physician or other administrator managing a health care facility must attend to both the practical matters of reducing risk to people as well as satisfying regulatory agencies through appropriate documentation and follow-through. This appendix focuses on the procedures, policies, and equipment recommended for reducing risk to health care workers (HCWs) and patients, as well as meeting statutory regulations, especially as they apply to office procedures. It also outlines the requirements of an "Exposure Control Plan" as required for all health care employers by OSHA. Be aware that OSHA focuses only on employee protection.

# **INFECTION PREVENTION STRATEGY: WORKERS**

Recommended guidelines for prevention of infections in HCWs encompass four domains: (1) formulation and implementation of site-specific policies in infection control (an "Exposure Control Plan"), (2) HCW screening and education at time of employment, (3) HCW immunization at the time of entry into an employment situation with risk, and (4) HCW use of barrier protection at

time of risk of exposure. All aspects of the prevention strategy require regular reevaluation and updating as well as ongoing education of all workers.

The elements of an OSHA-compliant "Exposure Control Plan" are detailed in the statute and must be adapted to each individual site. Twenty-four states have adopted their own occupational safety guidelines and enforcement policies. They are usually identical to the federal guidelines, but you should check specifics for your state. In general, your plan must include common policies (Table F-1) as well as documentation of orientation and ongoing training of personnel. It must also delineate policies for record keeping (employee health screen information, records of training, records of any incidents or injuries, and so forth). The plan must be in written form and available to all employees. There should be evidence of periodic review of the plan for currency and accuracy. Proprietary agencies, including some medical supply marketers, sell "kits" for preparation of a site's "Exposure Control Plan" that include templates customizable to a site. Federal regulations require that all HCWs be evaluated initially with a health inventory. This should include determination of suitability for a position at risk for infectious exposure as well as determination of the worker's immune status for vaccine-preventable illnesses (OSHA's only required immunization policy is for hepatitis B virus vaccine). These health screens must be recorded in written form, and workers must be reevaluated periodically. Each employee in the facility should have a health record available and updated with the necessary information. This health record should be maintained separately from the employee's other employment record and must be maintained for 30 years by OSHA regulations. At this initial evaluation, a determination of the need for additional vaccination should be made. Current CDC recommendations are listed in Table F-2.

After initial assessment, infection control in HCWs continues with education. Simple hand washing is the most important activity in reducing transmission of infections in the workplace. Education about policies such as sharps disposal, no recapping of needles, and prompt reporting of injury is crucial. Health care facilities should take steps to ensure initial orientation to infection control policies for all employees and periodic reinstruction of all established personnel. Policies should be written clearly and include supporting information so that employees can understand the rationale for the policies. Employees should be evaluated for the specific risk associated with their particular job and special education for risk reduction implemented and documented.

An often overlooked aspect of an infection control strategy is the immunization of HCWs who are at risk for vaccine-preventable diseases. Appropriate use of vaccines in susceptible individuals can not only help prevent nosocomial infections in HCWs but also reduce loss of workdays because of isolation following potential exposures. In addition, prevention of infection through optimal use of vaccinations and laboratory determination of immune status is much more cost effective than case management following an exposure in a nonimmunized HCW. Immune status of all health care

TABLE F-1 Infection Control Policies for a Typical Physician's Office			
Area	Specific Details to Include		
Handwashing	Rules for areas with and without running water; handwashing before and <i>after</i> eating, drinking, smoking, applying cosmetics, handling contact lenses, or using the restroom as well as between patients		
Contaminated sharps	Both disposable and reusable sharps; no recapping of needles or using one-handed recapping technique; disposal of filled sharps containers		
Areas for eating, drinking, smoking, and applying cosmetics	Application of lip balm		
Contaminated equipment	Manufacturers' guidelines for disinfection		
Personal protection equipment (PPE)	Use of gloves, gowns, masks, goggles, and impervious aprons		
Cleaning/disposal of PPE	Method of documentation of cleaning		
Contaminated spills	Choice of cleaning agent		
Contaminated laundry	Bagging in room of use; use of closed bags for transport		
Employee hepatitis B virus vaccination	Hepatitis B vaccine declination form (OSHA Regulation, see Fig. F-1)		
Postexposure evaluation and follow-up	Procedure to document details of injury; testing of both employee and source individual; document counseling; procedure for administration of antiretroviral agents		
Employee training	Initial and ongoing training schedule		
Specimen handling	Separation of food items and specimens; use of gloves when handling specimens		
Triage of patients	Carefully screen patients for communicable diseases at check-in so that susceptible workers can avoid contact, and infectious patients can be removed promptly from contact with other waiting patients		

facility personnel should be recorded at initiation of employment, and the hepatitis B vaccination series should be made available to all susceptible employees (OSHA Regulation, 2001). An employee who declines the vaccine should sign the Hepatitis B Vaccine Declination Form (Fig. F-1). Barrier protection using personal protection equipment (PPE) is the last line of prevention for HCW exposure to potentially infectious material. All HCWs must use appropriate PPE for the task at hand. In summary

- Gloves should be worn when contact with any blood, body fluids, mucous membranes, or broken skin is anticipated or possible; this exposure includes contact with soiled items or surfaces and performing venipuncture.
- Masks and eye shields should be worn when splashes of blood or body fluids are possible or during procedures in which blood, body fluids, or tissue could be aerosolized.
- Gowns or impervious aprons should be worn in situations in which blood or body fluids could contaminate the HCW's clothing.
- Gowns, aprons, and gloves must be changed and discarded between patients.
- Mouth-to-mouth ventilation should be performed using a "mouthto-mask" ventilation device with no direct contact between the patient's mouth and the HCW's.

See Table F-1 for an example of an office guideline, and consult the OSHA statute for a detailed discussion of the regulations.

# **ENVIRONMENTAL CONSIDERATIONS**

Environmental considerations for prevention of infection from the HCW to the patient (or between patients) can be defined in three areas:(1)surfacedisinfection,(2)instrumentsterilization/disinfection, and (3) policies regarding function of actively infected HCWs in the health care facility.

A full discussion of all the issues in the choice and use of agents for disinfection of surfaces and instruments is beyond of the scope of this appendix. The Association for Professionals in Infection Control and Epidemiology, Inc. (APIC) has published a comprehensive guideline that can serve as a reference for further details. In general, it is important to know some of the history of this area in order to understand some of the terminology. A classification developed in the 1960s by E. H. Spaulding is still used today to determine appropriate levels of decontamination of medical surfaces and equipment.

In general, Spaulding divided devices into three levels of decontamination. The first level is *critical*, meaning that the device enters sterile tissue or the vascular system. These devices must be *sterilized*, that is, devoid of microbial life, including spores. This can be accomplished by heat, ethylene oxide gas, and a number of immersion techniques. For many physicians' offices, a small autoclave accomplishes the task of rendering reusable devices and instruments sterile between patients. For critical instruments that cannot be subjected to heat or for facilities in which use of heat or ethylene oxide sterilization is not available, several immersion fluids are available.

TABLE F-2	Summary of Advisory Committee on Immunization Practices Recommendations for Health Care
Workers, I	Including Special Conditions

Worker Status	Hepatitis B Recombinant Vaccine	Influenza Vaccine	Measles/Mumps/Rubella Live-Virus Vaccine	Varicella Zoster Live-Virus Vaccine
Healthy, nonpregnant	R	R	R	R
Pregnant	R	R	С	С
HIV-positive	R	R	R*	С
Severe immunosuppression	R	R	С	С
Asplenia	R	R	R	R
Renal failure	R	R	R	R
Diabetes	R	R	R	R
Alcoholism and cirrhosis	R	R	R	R

C, Contraindicated; HIV, human immunodeficiency virus; R, recommended.

Adapted from Centers for Disease Control and Prevention. Immunization of Health-Care Workers: Recommendations of the Advisory Committee on Immunization Practices (ACIP) and the Hospital Infection Control Practices Advisory Committee (HICPAC). MMWR 46(No. RR-18):36, 1997. Available at http://www.cdc.gov/mmwr/preview/mmwrhtml/00050577.htm.

<sup>\*</sup>Contraindicated in persons with HIV infection and severe immunosuppression.

#### **Hepatitis B Vaccine Declination Form**

I understand that due to my occupational exposure to blood or other potentially infectious materials I may be at risk of acquiring hepatitis B virus (HBV) infection. I have been given the opportunity to be vaccinated with hepatitis B vaccine, at no charge to myself. However, I decline hepatitis B vaccination at this time. I understand that by declining this vaccine, I continue to be at risk of acquiring hepatitis B, a serious disease. If in the future I continue to have occupational exposure to blood or other potentially infectious materials and I want to be vaccinated with hepatitis B vaccine, I can receive the vaccination series at no charge to me.

Signature of employee

Date

Figure F-1 Hepatitis B Vaccine Declination (Mandatory) form. (From OSHA [Occupational Safety and Health Administration] Regulations [Standards, 29 CFR Part 1910.1030] [56 Fed. Reg. 64,004, Dec. 6, 1991, as amended at 57 Fed. Reg. 12,717, April 13, 1992; 57 Fed. Reg. 29,206, July 1, 1992; 61 Fed. Reg. 5507, Feb. 1996].)

Manufacturers' recommendations for use of these solutions, with special attention to treatment time, should be followed closely.

The second level is *semi-critical* and applies to devices that touch mucous membranes. These instruments include endoscopes, endotracheal tubes, and laryngoscopes as well as thermometers. These devices must be subjected to *high-level disinfection*. Because many of these instruments cannot be subjected to heat, special cleaning devices and fluids must be used for their disinfection. It is important to follow manufacturers' recommendations completely to avoid incomplete disinfection as well as damage to the instruments. Again, thorough cleaning of instruments prior to disinfection is important. Routine changing of fluids and cleaning tools is an important part of an effective routine.

The third level of decontamination according to Spaulding is noncritical and includes stethoscopes, examination room surfaces, and bedpans. These items should be cleansed appropriately with agents that are known to kill most surface microbes without significant corrosion of the items or without being excessively toxic to the HCW. Typical agents in this category include alcohols (ethyl and isopropyl), household bleach (5.2% sodium hypochlorite), phenols, iodophors, and quaternary ammonium compounds. These agents are commonly sold by medical supply companies for use on surfaces. Manufacturers' guidelines must be understood and followed. Be aware of the corrosive nature of some of these products on certain surfaces, and follow instructions for protection of HCWs from any potentially toxic fumes.

An important concept in the handling of reusable instruments is the direction of workflow. It is important that "clean" and "soiled" areas are separated and policies are established so that item flow does not risk contamination of "clean" items. There should be clearly defined areas for the receipt of contaminated items with physical barriers preventing accidental contamination. Policies for maintaining these processing standards should be clear to all workers.

Use and maintenance of autoclaves in an office should be governed by policies and routine, reflecting good infection control practices. The first step in sterilization of instruments is thorough cleaning (removal of surface debris) of all instruments to be sterilized. Biologic and chemical indicators for use in heat sterilizers should be used and checked consistently. Temperature and pressure and results of indicators should be recorded in a log form. Remember, biologic indicators require use of a manufacturer-recommended incubator for proper use.

Regarding transmission of disease from the ill or potentially ill HCW to the patient, the health care facility's administration is responsible for development and implementation of policies to address this issue. At times, such policies may result in restriction of HCWs from patient contact; therefore, it is important that policies be designed to encourage reporting of exposures and illnesses protecting wages, benefits, and job status if possible. The policies should reflect exclusions resulting from both acute infection and known exposure. The policies should be clear regarding who in the facility is responsible for making isolation exclusions.

The decision making falls into two broad categories that require quite different management and follow-through. For chronic bloodborne communicable diseases such as HIV and HBV, the CDC recommends the HCW "...not perform exposure-prone, invasive procedures until counsel from an expert review panel has been sought, which will determine under what circumstances the worker may or may not perform exposure-prone, invasive procedures." Exposure-prone invasive procedures include those that involve manipulating a needle inside the body or placing the fingers and a needle or other sharp instrument in a poorly visualized or highly confined anatomic site. The CDC recommends no restrictions for workers with chronic hepatitis B if hepatitis B e antigen becomes negative and currently recommends no restriction regarding workers with hepatitis C. Each facility should develop its own policy regarding HIV and hepatitis B- and C-infected workers.

For more acute disease entities, the CDC has developed guidelines that can be adapted for most facilities (Table F-3). The guidelines summarize recommended work restrictions including duration. These guidelines apply to both exposure and infection with the disease. They should always be compared with any local or state guidelines that may apply in your area. Consideration of your facility's patient population and the worker's level of patient exposure is important. In jobs in which close contact with patients is unlikely, a worker might be able to remain on the job but could use certain precautions (such as wearing a mask) and still not jeopardize patients or coworkers.

# **CONCLUSION**

It is important that the leadership of every health care facility, regardless of size, become familiar with the standards and regulations regarding infection control in the workplace. The facility must formulate and implement policies to protect health care workers as well as patients from communicable diseases. These policies should reflect current guidelines from the CDC and comply with regulations promulgated by OSHA. In addition to this appendix, the infection control officer of your local hospital should be considered as an ally and information source in development or review of policies and procedures for your particular site.

TABLE F-3 Summary of Suggested Work Restrictions for Health Care Workers Exposed to or Infected with the Most Common Acute Communicable Diseases of Importance in the Ambulatory Setting

Disease/Problem	Work Restriction	Duration
Conjunctivitis	Restrict from patient contact and contact with the patient's environment	Until discharge ceases
CMV infection	No restriction	
Diarrheal diseases Acute stage	Restrict from patient contact, contact with the patient's	Until symptoms resolve
Convalescent stage (Salmonella spp.)	environment, and food handling Restrict from care of high-risk patients	Until symptoms resolve; consult with local health agencies regarding need for negative cultures
Enteroviral infections	Restrict from care of infants, neonates, and immunocompromised patients and their environments	Until symptoms resolve
Hepatitis A	Restrict from patient contact, contact with the patient's environment, and food handling	Until 7 days after onset of jaundice
Herpes simplex Genital Hands (Whitlow) Orofacial	No restriction Restrict from patient contact and contact with the patient's environment Evaluate for need to restrict from care of high-risk patients	Until lesions heal
Measles Active Postexposure (susceptible)	Exclude from duty Exclude from duty	Until 7 days after rash appears From 5th day after first exposure through 21st day after last exposure or 4 days after rash appears
Meningococcal infection	Exclude from duty	Until 24 hours after start of effective therapy
Mumps Active Postexposure (susceptible)	Exclude from duty Exclude from duty	Until 9 days after onset of parotitis From 12th day after first exposure through 26th day after last exposure or until 9 days after onset of parotitis
Pediculosis	Restrict from patient contact	Until treated and observed to be free of adult and immature lice
Rubella Active Postexposure (susceptible)	Exclude from duty Exclude from duty	Until 5 days after rash appears From 7th day after first exposure through the 21st day after last exposure
Scabies	Restrict from patient contact	Until cleared by medical evaluation
Staphylococcus aureus infection Active, still draining lesions Carrier state	Restrict from patient contact, contact with patient's environment, and food handling  No restriction unless personnel are epidemiologically linked to transmission of the organisms	Until lesions have resolved
Streptococcus, group A infection	Restrict from patient contact, contact with patient's environment, and food handling	Until 24 hr after adequate treatment started
Tuberculosis Active disease PPD converter	Exclude from duty No restriction	Until proved noninfectious
Varicella Active Postexposure (susceptible)	Exclude from duty Exclude from duty	Until all lesions dry and crusted From 10th day after first exposure through the 21st day (28th day if VZIG given) after last exposure
Zoster Localized in healthy person Generalized or localized in the immunocompromised person	Cover lesions, restrict from care of high-risk patients Restrict from patient contact	Until all lesions dry and crusted Until all lesions dry and crusted
Postexposure (susceptible)	Restrict from patient contact	From 10th day after first exposure through the 21st day (28th day if VZIG given) after last exposure, or if varicella occurs, until all lesions dry and crusted
Viral URI, acute febrile	Consider excluding from the care of high-risk patients or contact with their environment during community outbreak of RSV and influenza	Until acute symptoms resolve

CMV, cytomegalovirus; PPO, purified protein derivative; RSV, respiratory syncytial virus; URI, upper respiratory infection; VZIG, varicella zoster immunoglobulin. ## **APPENDIX G**

# NEOPLASMS OF THE SKIN: ICD-9 DIAGNOSTIC CODES

John L. Pfenninger

- For excision and repair CPT codes, see Chapter 22, Laceration and Incision Repair. Understand that "shave excisions" and "biopsies" have their own CPT codes.
- The following ICD-9 codes are only for neoplasms originating in the skin. Other, subcutaneous tumors have their own codes (see the section on Selected Tumor Codes).

		Maligna	nt			
Site	Primary	Secondary	Carcinoma in situ	Benign	Uncertain Behavior	Unspecified
Skin NEC	173.9	198.2	232.9	216.9	238.2	239.2

Wrist	173.6	198.2	232.6	216.6	238.2	239.2

NEC, neuroendocrine carcinoma.

<sup>\*</sup>Intra-anal lesions have separate codes.

<sup>†</sup>Melanoma skin sites use the 172.X codes, where "X" notes the site on the skin. See the ICD-9 code book. Acceptable, but less accurate, coding would be to use the generic "primary, malignant" category by site.

From International Classification of Diseases, rev 9: ICD-9-CM 2003, 6th ed. Ingenix/St. Anthony Publishing, 2003.

#### **SELECTED TUMOR CODES**

Lesions below the skin have their own ICD-9 diagnostic codes depending on the location. They are divided into similar categories including the following:

- Malignant
  - Primary
  - Secondary
- Benign
- Uncertain behavior
- Unspecified

Each lesion must be looked up individually. Some examples of benign tumors:

- 215.0 Neoplasm of the face
- 215.2 Neoplasm of the shoulder
- 215.7 Neoplasm of the trunk

Another way of coding some of these lesions would be more specific:

- 214.0 Lipoma, face, subcutaneous (SQ)
- 214.1 Lipoma, other, SQ

Some examples of malignant tumors:

- 171.0 Malignant tumor of the face
- 171.2 Malignant tumor of the shoulder
- 171.7 Malignant tumor of the back

It is important to recognize that skin neoplasms are coded distinctly differently than tumors below the skin. For excision of these tumors, a separate set of CPT codes is used, based on the size (usually <3 cm or >3 cm) and whether they were subcutaneous or subfascial, or whether a radical removal/excision was required. See Chapter 22, Laceration and Incision Repair.

Using the "unspecified" codes for either skin neoplasms or for subcutaneous tumors is likely to generate rejections from insurance carriers or requests for further information.

# PEARLS OF PRACTICE

John L. Pfenninger • Grant C. Fowler

"I don't think I'm unique. Anybody can do quite a lot by refusing to give in to limitations."

Christopher Reeves

- 1. When repairing or removing *scalp lesions*, remember that patients do not like to have their hair shaved unless it is absolutely necessary. *Remove minor lesions without shaving*. To keep the hair from continually falling into the operative field, use antibiotic ointment to flatten it down. Apply the ointment after performing the usual preparation.
- 2. The majority of skin lesion removals are performed either with a shave technique or with curettement and cautery. Moist healing is the key to an excellent long-term outcome with minimal scarring. Eschars (scabs) impair the normal healing process. Healing tissue is much like a new lawn: It needs to be kept moist. Unless under clothes, wounds should remain without a dressing, except for ointment, when possible. If under clothes, wounds will obviously need to be covered with an adhesive strip or other dressing. Likewise, facial areas will need to be covered at night. Basically, the patient just gently washes the area three to four times a day with mild soap and water and applies an ointment afterward. It does not necessarily have to be an antibacterial ointment; even petrolatum (Vaseline) will do. Avoid neomycin, hydrogen peroxide, or povidine-iodine (Betadine). The deeper the open wound, the longer it will be necessary to keep the area moist (generally 7 to 14 days).

With sutured wounds, have the patient gently wash the area within 12 hours and apply antibiotic ointment three or four times a day (unless tissue glue or Steri-Strips have been applied). Cover with other dressings only as noted previously. An easier method for the patient that causes less inflammation is to use a moist healing occlusive dressing such as Tegaderm. This is applied immediately after excision (or laceration repair) and left in place until the sutures are removed, unless blood accumulates and then it can be changed.

See the sample patient education handout online at www. expertconsult.com.

- 3. There is no need to stop warfarin (Coumadin), clopidogrel (Plavix), or aspirin for routine dermatologic procedures. Several articles have been published documenting that embolic events occur during the period of stopping and restarting the medications. Meticulous attention must be paid to hemostasis. Clotting parameters should be checked before significant excisional surgery. However, for shaves, curettements, and most excisions, it is unnecessary to stop any of these medications or to check laboratory results (see Alcalay 2001; Schanbacher and Bennett 2000).
- 4. Bridge therapy is for patients on chronic anticoagulation who need elective surgery. It is defined as protected periprocedural discontinuation of warfarin (Coumadin) 3 to 4 days before performing procedures in patients at high risk for thromboembolism. The first step is initiation of low-molecular-weight heparin (LMWH) at full therapeutic dose on the day after warfarin is stopped (e.g., no warfarin Monday, begin LMWH on Tuesday morning). The patient receives the last dose of LMWH the morning of the day

before the procedure. Then the invasive procedure or surgery occurs. Warfarin and LMWH are reintroduced later that day if deemed safe and hemostasis has been achieved. Subsequently, LMWH is discontinued after discharge once the international normalized ratio (INR) has been therapeutic for 3 or 4 days.

Bridge therapy is used for patients with a high risk of atrial fibrillation (i.e., for cerebrovascular accident [CVA] prevention), prosthetic valves, a recent (last 3 months) thromboembolic event, indications for prolonged warfarin therapy, or a history of a hypercoagulable state.

This therapy avoids prolonged hospitalization, changing of anticoagulation while preparing for surgery, vitamin K administration, and a prolonged period without anticoagulation with the attendant risk for thromboembolism.

The disadvantages are cost of LMWH, self-injection, and a relative lack of reversibility. (From James Lile, pharmacist, MidMichigan Medical Center, Midland, Mich.)

- 5. For those who want to diminish the pain of anesthetic injections, add a little bicarbonate to the anesthetic (1 part bicarbonate to 9 parts of anesthetic). Anesthetics sting with injection because of a low pH; this supposedly inhibits bacterial growth but at the same time is uncomfortable. The bicarbonate takes the "sting" out of the injection. Also, use a small needle (27 or 30 gauge), use warm solutions, and inject slowly. Injecting deeper into the dermis will cause less pain, but it takes longer for the anesthetic to work. Injecting more superficially will hurt a little more, but the anesthetic will work faster. Do not add sodium bicarbonate to bupivicaine (Marcaine) because it will precipitate in a neutral pH.
- 6. When injecting lidocaine into an area that needs to be palpable later (e.g., to feel a foreign body, find a vas during vasectomy), you can massage the lidocaine into the skin so that it does not obstruct your fine touch. Alternatively, perform a nerve block or a field block, thus eliminating any anesthetic in the area.
- 7. Melman and Siegel (1999) have shown that it is perfectly okay to draw up anesthetic solutions in syringes up to 7 days before use. There is no increased bacterial contamination or growth, and the anesthetic still functions. We used to pull up our syringes at the beginning of the day and then discard them at the end of the day, but there was no need. We now fill numerous 1-mL syringes, date them, and continue to use them throughout the week. It is much more efficient for the nurse to pull up multiple syringes than to do just one at a time. It is inefficient for the physician to spend time pulling up anesthetic!
- 8. Consider using the MadaJet for local injections. It is a small handheld "gun" that "injects" medications without a needle. It is only for superficial injections but can be used to treat keloids and hypertrophic scars with steroids, etc. It has also been adapted for the no-needle vasectomy (Wilson 2001). It is available from Delasco at 1-800-831-6273 (website: www.delasco.

- com) and Advanced Meditech International (1-800-635-2452 or www.ameditech.com).
- 9. When someone complains of an *allergy to local anesthetics* (including Novocain), he or she has usually received an *ester*. To date, there have been no reported allergic reactions to the *amides* such as lidocaine (Xylocaine). Some patients still report that they have had a reaction to lidocaine or to "all local anesthetics." In these instances, they have usually had medication drawn from a multidose vial, which has preservatives (parabens) in it. If someone does complain of having a history of local anesthetic reaction, use single-dose vials of lidocaine and he or she will be able to tolerate it without incident. It is inexpensive and helpful to have around. (Also see pearl 43.)
- 10. Advanced Meditech International (AMI) has designed a small anesthetic bottle holder that mounts on the wall (VE-11 Handzfree anesthetic bottle holder). The cost is only around \$40, and in our office it is indispensable. It holds the anesthetic where it is readily available and makes filling syringes an easy task. It also allows the entire staff to see how much anesthetic is left in the bottle. There is nothing more frustrating than pulling out the drawer with the anesthetic solution and finding that the bottle is empty! Contact AMI at 1-800-635-2452 (website: www. ameditech.com).
- 11. Physicians must maximize their time in the office. Inefficiency has to be eliminated. I (JLP) literally try to find 30 seconds to save on every patient. Having the syringes prefilled (see pearl 7) saves time! When I discuss this at our courses, initially there are chuckles about "the 30 seconds." Then I do the math. I am usually able to see 20 to 25 patients in a day. If I save 30 seconds on each one, this is 10 to 12 minutes per day, which actually allows an extra office visit or procedure in a day. If you work 4 days a week, that is four extra visits a week. Working 45 weeks out of the year, this amounts to 180 visits. If you average \$100 per visit, that is an extra \$18,000 per year. At \$150 per visit, that is an extra \$27,000 a year—just for saving 30 seconds per patient! If you see more than 20 to 25 patients per day, even more can be earned. Efficiency is essential.
- 12. OSHA has numerous requirements for a safe office practice. One of them is the use of *fluid-resistant coats* when performing procedures. My (JLP's) staff ordered these coats for me. They made an error and selected the coats with the *knit cuff sleeves*—how fortuitous! As residents rotate through the office, they frequently have the large sleeves that look like the old nuns' habits! The ends of the sleeves hang down 8 to 10 inches from the wrist. Subsequently when they reach for an instrument, the sleeve often drags across the sterile field. Knit cuffs help protect a sterile field and I highly recommend them. The fluid-resistant coats are also beneficial in that any fluid that gets on them is easily wiped off, and the coats last a long time. And remember, not using them could make you liable for a \$25,000 OSHA fine!
- 13. I (JLP) have found that a *good way to explain the risk of complications* to patients is to use the example of a lottery. In medicine, you "never say 'never' and never say 'always'". And yet, the likelihood of some things happening is almost "never." So I ask the patients if they play the lotto. Most of them do sometimes. I then ask them if they will ever win. Most of them say, "No." I then reply, "But you could, right?" and they say, "Yes." I then explain that many complications are just like that. It is not going to happen, but if you play "the lotto," it could. This example really helps them understand the risk of complications. (So one day, a patient called up and said that he had won the lotto. A resident who was working with me got excited. I had to tell him that that wasn't good!)
- 14. I (JLP) have always liked to explain to patients how the particular surgery or procedure went. I try to be very honest. I will often say, "Technically, things went well," or "Technically, this case was quite difficult and we had a few problems." *Patients appreciate honesty*. They know things cannot go perfectly all the

- time. I never tell patients that it was "an easy case"; should complications arise, they think you have done something wrong. If you tell them, however, that the case was difficult, you are not looked on so negatively if complications do arise. Also, if there are no complications with tough cases, they think you have done a better job. The point of this tip: *Never overstate how well something went*. Just say that technically things went well, but complications can still occur.
- 15. I (JLP) have done perhaps 125 or 130 medicolegal cases as an expert witness. A brief tip to avoid litigation: When a patient comes in to the office, always review the last note to see what the complaint was. Ask the patient if the problem has resolved. Just jot a little note (e.g., "breast mass resolved" with the date, or "rectal bleeding gone" with the date, or perhaps "cough cleared"). Many times patients come into the office for a new complaint and the physician forgets about a significant old complaint, but the patient thinks the physician remembers. Just looking back at the record and asking that simple question could have cleared many physicians from later malpractice suits. You would also be amazed how many problems persist that the patients don't complain about and physicians subsequently overlook.
- 16. The *height of your examination table* is extremely important. When I (JLP) opened a new office, I purchased a table that was only 2 inches higher than my current one. I found that older patients had a difficult time getting up on the table. The lowest height can be no more than 24 inches for these patients. A *power table is essential* if you are going to be doing procedures.
- 17. There are really few medical emergencies in a physician's office. However, one of them can be anaphylaxis (see Chapter 220). In addition to the Banyan kit ("a crash cart in a suitcase") that is mentioned there, I keep an EpiPen taped to one of our cupboard doors. Right beside it is a vial of atropine and some ammonia salts. I have only had occasion to use the EpiPen once after an injection with Candida. However, people were not rushing around looking for the proper dose of epinephrine, or the syringe, or even trying to find the Epi! We just opened the cupboard door where it was taped, and gave the injection. Consider having these three medications readily available in your office, especially if you perform a significant number of procedures or injections. The Banyan Kit is the most cost efficient, safe, and practical way to maintain resuscitation capabilities in your office.
- 18. I (ILP) have developed a simple method for determining whether or not a patient is likely to faint during a procedure. I think vasovagal symptoms have occurred more with vasectomy than with any other procedure I do. Subsequently, I ask the patient how well they tolerate pain. The options are "well," "okay," and "poorly." I also ask them if they have a tendency to faint or if they faint when they see blood. If the answer is that they tolerate pain well, I just use a local anesthetic. If they tolerate pain "okay," I'll offer them 10 mg of diazepam an hour before significant procedures (e.g., vasectomy). If they tolerate pain poorly or if they say they have a tendency to faint, in addition to the 10 mg of diazepam orally, I'll give 0.5 of atropine intramuscularly on arrival to the office. (I'll often listen to the partner's answers, too, in addition to the man's response!) Since using this approach, I haven't had a single patient have a vasovagal episode while on the table during a vasectomy or any other procedure.
- 19. In the past it was felt that epinephrine should not be used in fingers, nose, penis, and toes. These are end-arterial and it was thought that the vessels could go into spasm leading to necrosis. As with many past "teachings," this was an empirical one. Studies have not found this to be true and "epi," in the doses used in local anesthetics, appears to be safe. By reducing blood flow, it may improve visualization of the anatomy and aid in closure. See the references in Chapter 4, Local Anesthesia. Interestingly,

- these very same areas (in addition to the anal and vulvar regions) are very sensitive. Warn patients that injections are very uncomfortable.
- 20. Now that I (JLP) receive numerous referrals from primary care physicians, I think the *single largest error that I see involves anal complaints*. Frequently patients are sent to me for "hemorrhoids" and I have found fissures, fistulas, cancers, polyps, warts, and solitary anal ulcers. It seems that for both physicians and patients, when there is any rectal bleeding, it is automatically assumed to be "hemorrhoids." My only plea would be to look. Many times just spreading the glutei will give you the diagnosis. If nothing else, *perform a digital examination and a good anoscopy*. In my opinion, the only anoscope to use is the *Ive's slotted anoscope*. The long cylindrical scopes just do not allow adequate visualization for anorectal complaints. If you as a clinician do not feel comfortable evaluating anorectal complaints, then don't treat them; but don't make a diagnosis for the patient. Just send them to a clinician who is willing to evaluate them.
- 21. It always amazes me (JLP) that when patients have anal complaints, one of the first things they are treated with is *hydrocortisone cream for presumed hemorrhoids*. I ask at many of my courses how many physicians treat varicosities of the lower extremities with steroids. Not surprisingly, no one does. Then why does everyone treat "hemorrhoids," which are engorged veins, with steroids? It is an appropriate thing to do if the hemorrhoids are inflamed, but probably less than 10% of those with rectal bleeding truly have inflammation. Again, the rule should be to *examine the patient first before making the diagnosis of hemorrhoids* and to use hydrocortisone preparations only if inflammation is present.
- 22. A study was performed that looked at absorbable vs. nonabsorbable sutures after a punch biopsy. The study found that the cosmetic results 3 months later were equal.
- 23. When performing a punch biopsy of the skin, routinely use a 3-mm punch. The advantage is that it provides enough tissue for diagnosis but will not need suture closure. A 4-mm punch often requires a suture, and a 5-mm punch definitely does. However, when you close a circular lesion that is 5 mm with suture, you will end up with dog ears on each side. A 2-mm punch may not be adequate for diagnosis. The tissue is often macerated and it is difficult to give the pathologist a good specimen. If a 3-mm punch defect is not closed, there will usually be no visible scar remaining. At the very worst, the patient may end up with a small acne pockmark-like lesion.
- 24. Performing a needle biopsy does not spread malignant cells in the needle track. It is safe even with nodes that contain metastatic melanoma. Similarly, shaving a nevus does not lead to malignant transformation.
- 25. The work-up for abnormal uterine bleeding is now generally managed with an endometrial biopsy (see Chapter 143). In the past, when dilation and curettage (D&C) procedures were performed, a "fractional" D&C was recommended. This meant that an endocervical curettage preceded the D&C. When the studies confirmed that endometrial biopsies alone were an adequate method of evaluating abnormal uterine bleeding, many dropped the endocervical curettage (ECC). However, an ACOG Bulletin recommends that the evaluation for abnormal uterine bleeding includes an ECC along with the endometrial biopsy. If these studies are negative and symptoms resolve, no further work-up is necessary. Although many of us have jumped to performing vaginal ultrasounds to evaluate abnormal uterine bleeding, there is an ethnic variance. Although the safe cut-off quoted is 5 mm of endometrial stripe, cancers have been found with only 3 mm of stripe in Japanese patients. Endometrial biopsy with ECC is still, in my (JLP's) estimation, the best way to evaluate abnormal uterine bleeding. The caveat is to be sure that the bleeding is "uterine" and that other potential causes are not overlooked.

- 26. Unless extensive stitching is to be done, sterile gloves are not needed for routine biopsies and most skin procedures.
- 27. A potential pitfall in interpreting Papanicolaou (Pap) smear results is to confuse atypical squamous cells of uncertain significance (ASC-US) with atypical glandular cells (AGC) and ASC-H (atypical squamous cells, high-grade lesion cannot be ruled out). Should a Pap smear come back with either AGC or ASC-H, it is imperative that the patient undergo a complete work-up, beginning with colposcopy. A consensus of studies shows that approximately 10% of patients with atypical glandular cells will have a cancer somewhere in the genital tract if indeed the cells are glandular and atypical. Another 10% to 15% will have high-grade dysplastic lesions. Be careful not to confuse atypical squamous cells with atypical glandular cells.
- I (JLP) have found that using the medium titanium hemoclips for performing vasectomies for fascial occlusion has been a timesaver, reduces the amount of bleeding present during the procedure, and is cost-effective. When introduced to the clips, I was resistant because I was going to have to incur another cost for the applicators. However, when suture material is used to perform the purse string around the fascia, the suture material also adds to the cost. In addition, bleeding often occurs with the insertion of the needle and it takes more time. Now, if there is bleeding in the fascial tissues around the vas, the titanium clip will readily and quickly control it. Patients often ask if the clips set off metal detectors. Since they are nonmagnetic, they do not. After a vas there will often be a slight palpable nodule, but by 3 months, patients are unable to detect any sign of the clip. If the patient continues to be worried, I just tell him to think about all the men who have fought in various battles during wars and who have shrapnel remaining in their bodies that does not cause them problems. This example usually eases the patient's mind.
- 29. In regard to billing, consider billing a handling fee (99000) when any labs are sent out to the hospital or other laboratory. Although many health maintenance organizations (HMOs), Medicare, and Medicaid may not reimburse it, a good portion of private insurance companies do. This covers your costs for documenting that the labs were sent out, for receiving the labs back, and for calling the patient. Even if only a small percentage of these fees is paid, it is still worthwhile charging for them.
- 30. "Insurance only" statements on your bills may get you into trouble. If you write "insurance only," it negates the insurance company's obligation to pay you. Treating certain patients, such as physicians and friends, for free is a medical tradition, but be careful. The changes in the law have made it a bad idea. The courts ruled in 1991 that physicians cannot charge insurance companies if they make this statement! (Don't you just love how everyone else tells us what to do? My suggestion: Be creative and be the doctor you want to be. You can figure out a way around this bureaucratic hassle.)
- 31. If you write off the patient portion of a Medicare bill, document well why it is a hardship case. Otherwise, Medicare can sue you and reclaim many of the fees they have paid you.
- 32. For Medicare, you cannot bill for treating your own family, which includes husband, wife, parents (even if you are adopted), children, siblings, step-relatives, grandparents, and domestic employees. It is okay for your partner to treat them, but not for insurance only. See pearl 30.
- 33. For those of you who are audited and your CPT coding is questioned, see King and Lipsky, 2000. They found that giving the same procedure to various coding experts resulted in various methods of coding out the procedure. Their conclusion was that CPT coding is not objective. This finding may help you in court!
- 34. I (GCF) suggest that you spend some quality time on coding and that you *buy a good book on coding*. While writing the foreign body removal chapter, I found that "10120" is the

- routine code for general removal of a subcutaneous foreign body. However, if the foreign body is located in the area of the shoulder, and is subcutaneous, the code is 23330 and the relative value units (RVUs) for this code are almost three times that for 10120! Knowing your coding and billing can markedly increase reimbursement. Consider the National Procedure Institute's *Reimbursement Manual*, which is updated annually (Phone: 1-866-NPI-CME1; website: www.npinstitute.com).
- 35. It is difficult for us to know exactly what to charge for each procedure. I (JLP) commonly refer to three books, which are updated annually: Yale Wasserman DMD Medical Publishers Ltd., Physicians' Fee Reference; The Health Care Consultants of America, Inc., Physicians Fee & Coding Guide; and the Ingenix National Fee Analyzer. Over the past 16 years, The National Procedures Institute has published a 53-page manual that is especially helpful for office practices. It lists all the common procedures normally performed by primary care physicians. For each CPT code, the RVUs and National Medicare, Michigan Medicaid, Michigan Blue Cross/Blue Shield, and the 50th percentile of the fees charged for each are listed. The three preceding references list fees based on national surveys of what physicians charge. The 50th percentile from each book is averaged together to come up with the 50th percentile charge. This would give at least a starting point to determine what to charge patients. For instance, what is reasonable for removing an ingrown toenail? A vasectomy? Sclerotherapy? Incision of a thrombosed hemorrhoid? Many physicians are undercharging. This manual, which is updated annually, does a lot of the work for you and is available from The National Procedures Institute (www.npinstitute.com).
- 36. Medicare did have a list of procedures in which they would reimburse a surgical tray. However, as of 2003, a surgical tray fee is not allowed. They claim to have incorporated the cost of the tray into the reimbursement for the procedure (in other words, a nice way to cut reimbursement without admitting that they've done it!). However, a surgical tray can still be charged to other insurances with the procedures that require more medical supplies (e.g., loop electrosurgical excision procedure [LEEP]). A surgical tray should never be charged for routine laceration repair or lesion removal, because it is indeed incorporated into the usual reimbursement fee.
- 37. With coding and billing multiple procedures performed on the same day, always have the biller code out the highest reimbursed procedure first. The procedures listed second, third, fourth, and fifth will be reduced by 50%. Those listed after that will be reduced to only 25% of the routine allowable charge. When seeing a new patient, it is essential to obtain a past medical history and evaluate the patient for other medical problems before performing the procedure. Proper coding and billing (current procedural terminology [CPT]) allows for payment of an initial office visit along with the procedure that same day. However, if the patient has been seen in the practice within the last 3 years, only the procedure can be charged. If the procedure is performed and another separate identifiable service has been provided (e.g., treatment for diabetes), a modifier 25 is used to receive reimbursement for both the procedure and the visit.
- 38. Some patients are sensitive to nonsteroidal anti-inflammatory drugs (NSAIDs) and will have increased bleeding when using them. A simple way to check for this sensitivity is just to obtain a bleeding time on and off the drug. If the bleeding time is prolonged while on the drug, patients are indeed sensitive.
- 39. It is amazing to us that more physicians are not *incorporating ultrasound into the office practice*. The newer units are cheaper, smaller, often can use a PC for the screen, and the definition has really been improved. Ultrasound is the modern stethoscope. If the stethoscope were developed today, we would call the HMO and get approval before we listen to someone's lungs to rule out pneumonia or congestive heart failure. Of course,

- approval for this procedure ("auscultation of the lungs") would probably cost \$24.99! Physicians should be embracing ultrasound technology as a means to enhance diagnostic capabilities, reduce delay in diagnosis, and actually bring down health care costs. It is reimbursed better than colonoscopy. After a 6-year review, one academic family medicine department found that a complete abdominal ultrasound was the best reimbursed procedure for the amount of time it took to perform it.
- 40. It concerns me (JLP) that so many physicians are jumping to the LEEP procedure to treat every dysplastic lesion on the cervix. Cryotherapy has worked for 30 years, and the documentation is excellent on efficacy and lack of complications. Cryotherapy fails only when there is a large extensive lesion or if the lesion goes into the os. It treats small CIN III lesions as well as conization (whether it be by laser, cold knife, or the LEEP procedure). Appropriate treatment with cryotherapy removes approximately 3 to 4 mm of cervix. Treatment with LEEP not only costs four to six times more (don't forget about the pathology fee to interpret the sample), but removes a minimum of 8 mm of cervix, and often 15 mm. Every study that has been done shows that in properly selected patients, cryotherapy of the cervix has the same cure rate as the LEEP procedure. (See, for example, Mitchell MF and colleagues, 1998; Pfenninger, 1999.). Some OB/GYN residency programs do not even teach cryotherapy anymore! I have a difficult time understanding the lack of science in medicine. Studies have documented that one in 17 women who have had a LEEP will experience a complication of pregnancy. See Chapter 149 on the LEEP procedure and Appendix K for further information.
- 41. A fantastic buying resource for dermatologic equipment is Delasco (available at 1-800-831-6273 or www.delasco.com).
- 42. Now do you want to read something really interesting? See Harris and colleagues, 1999, and Cha and colleagues, 2001. When treating patients, always try to emphasize treating the "whole" patient. We need to include surgery, medicines, x-rays, faith, and the person him- or herself in the healing process. The second reference is fascinating. Women attending an infertility clinic in South Korea were placed in the study to evaluate the effects of prayer. Half of the group was prayed for in the United States; the other half was treated routinely. The average fertility rate for the clinic was 27% for the previous 2 years. For the control group, the average rate of pregnancy was 28%. For the group that was prayed for, the average pregnancy rate was 56%! And the rest of the story: None of these patients or their doctors even knew that they were enrolled in a study, let alone that they were being prayed for in the United States (while they were in South Korea)! I don't think we understand extrasensory perception, clairvoyance, or the power of prayer. But just because we don't understand it doesn't mean we shouldn't use it!
- 43. When *injecting steroids* into joints, many of the steroids will precipitate when mixed with multidose vials of anesthetic. (See Chapter 192, Joint and Soft Tissue Aspiration and Injection [Arthrocentesis].) When the steroids precipitate, small crystals are then injected into the joint space. Some have postulated that this may be one of the causes for the *postinjection flare* some people experience. To avoid this complication, use single-dose vials of the anesthetics that lack parabens, and the steroid will remain in solution. It is the reaction with the parabens that causes the precipitation.
- 44. For those who have to treat *umbilical stump granulomas*, an article by Lotan and colleagues (2002) suggests using two ligatures rather than silver nitrate or other methods. The first ligature is tied to hold the stump and pull it up while a deeper ligature is placed to necrose the entire stump. It will fall off in 7 to 14 days and apparently has a better outcome than using silver nitrate.

- 45. Many people think that *taking photographs of pathology* (e.g., colposcopic findings) is beneficial and will help in a lawsuit situation. However, if you illustrate the findings, you are "the expert." In a photograph, a plaintiff's expert can contest what you identified. Drawing your findings may be more protective than photographing them.
- 46. Hypnotherapy can be a remarkable aid for controlling pain. Even if full hypnosis is not used, several relaxation techniques can be employed. Use a low monotone voice during painful or uncomfortable procedures. Avoid noisy interruptions by the staff or too much noise in the hallways and around the room. Soft, soothing music helps. Engaging the patient to help relax is important.
- 47. Compounding pharmacists are now making a comeback. They can make lollipops with lidocaine for anesthesia for oral procedures for children and with nicotine for those trying to stop smoking. "Rectal rockets" can make treatment of inflamed hemorrhoids easier. It is beneficial to learn what a compounding pharmacist can do.
- 48. Consider using a *skin hook* for vasectomies if you do not have the no-scalpel vasectomy instruments. It not only helps stabilize the vas, it is also reassuring that the vas is isolated, because fascia will flatten out or tear with pressure or tension. The skin hook can also be used for the minimally invasive sebaceous cyst removal. It can fixate the cyst sac, making it easier to invert and remove the sac itself.
- 49. Aesthetic procedures are really "hot" at this time. Not only are patients demanding them, but reimbursement is reasonable! A 15- or 30-minute therapy may reimburse as much as 3 hours in the intensive care unit working on someone with diabetic keto-acidosis or cardiogenic shock.
  - **CAUTION:** Many of the new instruments being offered are very expensive. Be sure to do your homework and determine what the maintenance fees will be per year. They can often run to \$10,000! Also, check on costs for supplies. Be cautious about the sale's pitch that "everyone will be running to your office." Many of us have been caught with equipment that generates cash—not for the doctor, but for the salesperson and the manufacturer!
- 50. The correct suture removal scissors can make a tough job much easier. Fine, tightly spaced sutures are often difficult to remove. It is worth the money to obtain Shortbent Stitch Scissors (3½ inch), curved, delicate (Miltex no. 9-101).
- 51. Good 2.5× to 3× optical loops do help to evaluate lesions, treat telangiectasias, and remove foreign bodies and sutures. Consider the Welch Allyn LumiView portable binocular microscope or flat surface magnifier (Welch Allyn, Inc., 4341 State Street Rd., Skaneateles Falls, NY 13153-0220; phone: 1-800-535-6663; website: www.welchallyn.com) or Keeler Loupes (Keeler, Clewer Hill Road, Windsor, Berkshire, SL4 4AA; phone: +44 (0)1753 857177; website: www.keeler.co.uk).
- 52. If you are having difficulty passing the sigmoidoscope or colonoscope at 25 cm, roll the patient all the way onto his or her back. This opens up the rectosigmoid junction and allows the scope to pass more easily (GCF).
- 53. Pay critical attention to proper patient positioning for the *slit-lamp examination*, because this will greatly facilitate obtaining a good examination. Most ocular pathology can be visualized appropriately under low magnification. Use of high magnification causes many users to miss the forests for the trees (From Christopher J. Bigelow, Midland, Mich.).
- 54. The extensor tendons have a significant excursion over the metacarpophalangeal joints. When lacerations occur in this area, carefully explore the underlying joint capsule for penetration throughout the entire arc of motion. *Unrecognized open joint injuries* can lead to significant infection if not treated appropriately. Bites or tooth lacerations (usually resulting from fistfights)

are especially bad. Use a low index of suspicion to start broadspectrum antibiotics.

A sizeable ganglion will typically transilluminate, thereby providing affirmation of the diagnosis (From David T. Bortel, Midland, Mich.).

55. Take a lot of time to establish rapport with a young female patient. The pelvic–genital examination itself takes no more than 5 minutes if the fearful patient trusts you long enough to be cooperative.

Don't expect the *child* who has just received *nasal midazolam* to sleep through your procedure. However, he or she will be cooperative.

Do not be tempted to use *DeLee suctioning* to clear the airway of particulate meconium in a newborn. Use an appropriately sized endotracheal tube (From David B. Bosscher, Knoxville, Tenn.).

- 56. Because fewer elective vaginal breech deliveries are being attempted, external cephalic version often provides the only option in attempting to avoid a cesarean section for breech presentation. If the initial attempt is unsuccessful, it is safe and cost effective to repeat the procedure in 1 week (From Andrew Coco, Hershey, Penn.).
- 57. Practice is the key to master *laceration and incision repair*. Begin with easy procedures and work up to larger excisions and skin flaps. Remember, it is okay to cut a suture that is incorrect and replace it (From William Jackson Epperson, Murrells Inlet, SC).
- 58. Consider event monitoring rather than Holter monitoring if the patient's symptoms are infrequent (From Dave Feller, Gainesville, Fla.).
- 59. Infarction q waves can be normal in limb leads III, AVL, and precordial lead  $V_1$ . ST segment elevation can be normal in healthy people but is ominous in the patient with chest pain (From Victor F. Froelicher, Stanford, Calif.).
- 60. The *cesarean section* is a lifesaving procedure that can be performed competently by family physicians with adequate training. Hospital privileges should be granted on the basis of experience with the operation and expertise of the surgeon.

The evaluation and selection of the patient for cesarean section is the most important step in the procedure. Knowledge of risk factors and indications for cesarean section is essential to proper patient care (From Rebecca H. Gladu, Houston, Tex.).

61. *Allergy screening* with only six to ten allergens can separate your allergic patient from nonallergic patients in a cost-effective way.

Immunotherapy is the patient's only "cure" for allergic rhinitis (From Harold Hedges, Little Rock, Ark.).

62. Every *spider vein*, no matter how small, comes from venous incompetence that can be traced back to a perforator. Always try to inject the vein that is closest to the source of this incompetence.

The longer postinjection compression (≤3weeks) is used, the better the result (From Stanley A. Hirsch, Pittsburgh, Penn.).

- 63. Many *paracentesis* kits have a 16- or 18-gauge needle for the paracentesis. This size is generally too large. A smaller needle can limit the amount of "leakage" of ascitic fluid from the entry site after the procedure is completed (From Kenneth Hu, Santa Monica, Calif.).
- 64. *Knee braces* should be used only in conjunction with a rehabilitation program incorporating strength training, flexibility, activity modification, and technique refinement (From Scott A. Paluska, Seattle, Wash.).
- 65. A tissue diagnosis is required for any *dominant breast mass*, even if the mammogram and ultrasound are negative.

Plan incisions carefully to achieve optimal cosmesis while preserving future surgical options if the lesion proves unexpectedly malignant (From Helen A. Pass, Royal Oak, Mich.).

- Electrical cardioversion, unlike defibrillation, is the administration of DC current synchronized with the R wave of the QRS complex.
  - Adequate anticoagulation of 3 weeks' duration and performance of an echocardiogram to evaluate left atrial diameter are generally considered necessary before *cardioversion of atrial fibrillation* of longer than 48 hours' duration (From David V. Power, Minneapolis, Minn.).
- 67. Send thoracocentesis fluid for protein, pH, and lactate dehydrogenase (LDH). Do not order other tests unless the fluid is an exudate (From Terry S. Ruhl, Altoona, Penn.).
- 68. When injecting a *trigger point*, inject directly into the area and then fan the needle to each side along the lines of the skin for best results. Trigger points are usually not round, but are oblong and amenable to fanning (From Gary E. Ruoff, East Lansing, Mich.).
- 69. To best visualize the sides and top of the bladder, the *cystoscope* should be rotated around the long axis of the scope rather than levered from side to side. This minimizes patient discomfort (From Andrew C. Steele, Travis AFB, Calif.).
- 70. Endometrial ablation significantly improves PMS, moodiness, and dysmenorrhea.
  - Postmenopausal bleeding resulting from hormone replacement therapy can be controlled completely by *endometrial ablation* (From Duane E. Townsend, Park City, UT).
- 71. When performing a punch biopsy, it is not necessary to obtain normal skin. The only time normal tissue is needed is with vesicular and bullous disease. For these entities, perform the biopsy on a new, fresh lesion right at the edge where it lifts up off the dermis. This location will afford the pathologist a better chance of making the correct diagnosis.
- 72. When using *plastic endometrial aspirators* for endometrial biopsy, it may be difficult to insert the unit into the os because of the flexibility of the tube. The aspirator can be "stiffened" by placing it in a freezer for a few minutes. When cold, it may easily enter the os. A full bladder often pushes the fundus posteriorly, opening the internal os if traction with a tenaculum has not succeeded in doing the same thing. Alternatively, a metal cervical dilator can be used.
- 73. The Centers for Disease Control and Prevention and other organizations have made the recommendation that, rather than frequent handwashing with soap and water, medical caretakers should use an antimicrobial hand gel. Various brands are available. In our office (JLP), we use Prevacare (Johnson & Johnson). It's hypoallergenic and has moisturizers. Several of my staff have eczema, and frequent handwashing was really exacerbating symptoms. Using the new gels without any water improved their symptoms while producing a better compliance and efficacy rate than soap and water. We get the hand pump container and feel it's well worth the cost.
- 74. Some patients are *allergic to iodine*, even in topical preparations (e.g., Betadine). Consider Techni-Care surgical scrub (Care-Tech Laboratories, Inc., St. Louis, MO [phone: 1-800-325-

- 9681]) with such cases. It's a broad-spectrum topical antiseptic microbicide with a 99.99% bacterial reduction in 30 seconds of contact. There is minimal to no dermal irritation. It's nonstinging and also safe on mucous membranes. The only difficulty is its tendency to foam up.
- 75. Children undergoing surgery develop more postsurgical scarring than adults. This is probably due to increased elasticity of the skin as well as an inability to get the children to limit activity. A report in the *Family Practice News* gives several pearls to limit the scarring:
  - Use more subcutaneous sutures and place them deeper. The report suggests that if you normally would use four sutures, then use eight for children! If the wound is fairly deep, consider using clear nylon for buried sutures, which will give permanent strength to the wound.
  - Leave in nondissolving running subcuticular stitches. If not visible, they won't hurt anything. If the stitch begins to work out, remove it later.
  - Place bulky dressings over the wound. This will inhibit some movement and help the child remember that surgery has occurred.
  - Immobilize the joints if there are any incisions over them.
  - Provide written instructions and emphasize the necessity of limiting activity.

# Universal Procedural Training in Family Medicine

Julie M. Sicilia • Stuart Forman

#### Box I-1. Procedure Categories

- A: All family medicine residency programs must provide training in each of these procedures.
  - A0: Residents will have the ability to perform these basic procedures either upon graduation from medical school or through normal residency experience. These procedures do not require specific documentation of training or numbers performed.
  - A1: All residents must be able to perform these procedures independently by graduation.
  - A2: All residents must have exposure to these procedures and be given the opportunity to be trained to perform them independently by graduation.
- B: These procedures are within the scope of family medicine and require focused training for residents to be able to perform independently by graduation.
- C: These procedures are within the scope of family medicine and may require additional training beyond the usual 3 years of training for family physicians to perform independently.

There has been a great deal of controversy over the fact that there are no universal standards defining which procedures are taught in family medicine residencies. In addition, there is a huge variance in regional and local areas. The inconsistent standardization of procedural training in family medicine residencies is the source of much consternation for patients, credentialing bodies, insurance companies, regulatory organizations, and other medical specialists, all of whom struggle to understand the scope of practice of family physicians, and which procedures family physicians are trained to perform.

The Society of Teachers of Family Medicine (STFM) Group on Hospital Medicine and Procedural Training met as a Task Force in 2007 and again in 2008 to propose a standard procedural training curriculum. The group consisted of 17 family physician educators (15 faculty members, 2 in private practice) from rural, suburban, and urban areas. Ten states were represented. During the first Task Force meeting, multiple procedures were considered and classified into different categories based on the need to be included in the curriculum (Box I-1). A paper was published in Family Medicine that outlined the agreed-upon core procedures. Recommendations were sent to the American Academy of Family Physicians (AAFP) Commission on Education for potential consideration by the Residency Review Committee (RRC). The group met again in 2008 and revised and updated the core procedures, which are printed as Table I-1. Advanced procedures were also discussed (Table I-2), and a summary was published in 2009 in Family Medicine.

TABLE 1-1 Core Procedures in Family Medicine				
Area of Care	A0*	Al <sup>†</sup>	A2 <sup>‡</sup>	
Skin	Remove corn/callous Drain subungual hematoma Skin staples Fungal studies (KOH) Laceration repair with tissue glues	Biopsies: punch, excisional, incisional Cryosurgery Remove warts, fingernail, toenail, foreign body Incision and drainage of abscess Simple laceration repair with sutures	Electrosurgery	
Maternity care		Spontaneous vaginal delivery, including Fetal monitoring Fetal scalp electrode IUPC and amnioinfusion Amniotomy Labor induction/augmentation First- and second-degree laceration repair Vacuum-assisted vaginal delivery	Third- and fourth-degree laceration repair Manual extraction of placenta	
Women's health	Wet mount, KOH Diaphragm fitting	Pap smear Vulvar biopsy Bartholin's cyst management Remove cervical polyp Endometrial biopsy IUD insertion/removal FNA of breast	Pessary fitting Paracervical block Cervical dilation Colposcopy Cervical cryotherapy Uterine aspiration/D&C

## **APPENDIX J**

# OUTLINE FOR A COMPREHENSIVE OPERATIVE NOTE

John L. Pfenninger

#### Procedure(s) performed:

(1) (2)

Surgeon:

Assistant:

Indications:

Preoperative diagnosis:

Postoperative diagnosis:

Findings:

Anesthesia:

Estimated blood loss:

Complications:

Pathology specimen sent?

Disposition:

Describe the patient's condition on the completion of the procedure and whether the patient was sent home, returned to the recovery room, and so on. If postoperative monitoring occurred, record that too.

#### Procedure:

Describe the surgical technique. Include the position of the patient; preparation; measurements; anesthetic administration; draping; details of the procedure itself, on the findings, any specifics; if tissue was removed, and if it was sent to the pathology department; methods of controlling bleeding, if applicable; closure (including types of sutures used, if applicable); dressing; and any other necessary pertinent information.

# MANAGEMENT GUIDELINES FOR ABNORMAL CERVICAL CANCER SCREENING TESTS AND HISTOLOGIC FINDINGS

Gary R. Newkirk

In September 2006 a group of 146 experts representing 29 organizations and professional societies met in Bethesda, Maryland, to develop revised evidence-based consensus guidelines for the management of women with abnormal cervical cancer screening tests. The process of revising these guidelines, which were originally published in their first version in 2001, was started in 2005 by the American Society for Colposcopy and Cervical Pathology (ASCCP) in collaboration with its partner professional societies and federal and international organizations. This effort culminated with the adoption and publication of two new consensus guidelines and a series of 12 management algorithms that provide suggested clinical responses to a variety of situations for both abnormal cervical screening testing and cervical histologic biopsy results (Figs. K-1 through K-3).

These guidelines are based on evidence whenever possible. However, for certain clinical situations, there is limited high-quality evidence, and in these situations the guidelines have, by necessity, been based on consensus expert opinion. The terms "recommended," "preferred," "acceptable," and "unacceptable" are used in these guidelines to describe various interventions. Table K-1 explains this terminology.

Several introductory caveats are provided with these guidelines and include the following: (1) clinical judgment should always be used when applying a guideline to an individual patient and (2) these guidelines should never substitute for clinical judgment. The expansion of these guidelines included management recommendations for special populations such as adolescent (younger than age 21 years) and pregnant women. Furthermore, given the potentially aggressive and increasingly prevalent nature of adenomatous or glandular precancerous and cancerous cervical disease, special guidelines provide specific management strategies for women with either cytologic or histologic glandular changes.

#### Management of Women with a Histologic Diagnosis of CIN 1 Preceded by HSIL or AGC-NOS Cytology

#### Management of Adolescent Women (20 Years and Younger) with a Histologic Diagnosis of Cervical Intraepithelial Neoplasia Grade 1 (CIN 1)

#### Management of Women with a Histologic Diagnosis of Cervical Intraepithelial Neoplasia (CIN 2, 3)

D

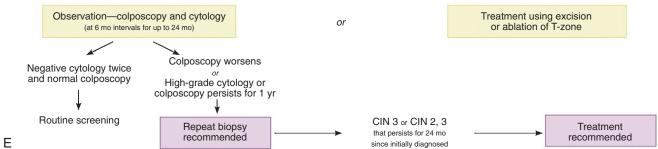

Figure continues on following page.

#### Management of Adolescent and Young Women with a Histologic Diagnosis of Cervical Intraepithelial Neoplasia Grade 2, 3 (CIN 2, 3)

### Adolescents and young woment with CIN 2, 3

Either treatment or observation is acceptable, provided colposcopy is satisfactory.

When CIN 2 is specified, observation is preferred. When CIN 3 is specified, or colposcopy is unsatisfactory, treatment is recommended.

#### Management of Women with Adenocarcinoma in situ (AIS) Diagnosed from a Diagnostic Excisional Procedure

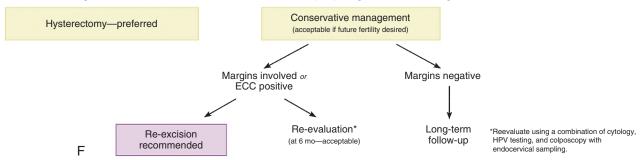

Figure K-2, cont. (A–F, Copyright 2006, 2007 American Society for Colposcopy and Cervical Pathology. All rights reserved. Available at http://www.asccp.org/pdfs/consensusf.)

#### Use of HPV Genotyping to Manage HPV HR Positive-Cytology Negative Women 30 Years and Older

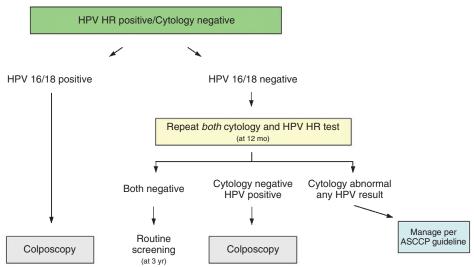

Figure K-3 Based on the data available at the time, the 2006 Consensus Guidelines included a recommendation that in cytology-negative women 30 years of age and older who are HPV DNA positive (for any of the 13 or 14 high-risk types of HPV detected by the high-risk HPV assays), molecular genotyping assays that detect HPV 16 and 18 would be clinically useful for determining which women should be referred for immediate colposcopy, and which could be followed up with repeat cytologic and high-risk HPV testing in 12 months. Because an FDA-approved HPV genotyping assay was not available in 2006, this recommendation was made contingent on approval of a HPV genotyping assay by the FDA. The first HPV genotyping assay was approved in March 2009. HPV, human papillomavirus; HR, high risk. (Copyright 2004, 2009 American Society for Colposcopy and Cervical Pathology. All rights reserved. Available at http://www.asccp.org/pdfs/consensus/hpv\_genotyping\_20090320.pdf; accessed 5/3/10.)

TABLE K-1 Terminology Used to Describe Interventions			
Guideline Terminology	Interpretation		
Recommended	Good data to support use when only one option is available		
Preferred	Option is the best (or one of the best) when there are multiple other options		
Acceptable	One of multiple options when there are either data indicating that another approach is superior or when there are no data to favor any single options		
Unacceptable	Good data against use		

The published algorithms for the 2006 Consensus Guidelines are presented as a valuable resource to clinicians who provide screening, diagnostic, and therapeutic management of cervical cancer precursors in women across the reproductive years and into the postmenopausal period. Appreciation is expressed to the ASCCP for granting inclusion of these guidelines. The complete guidelines are available at the ASCCP website and as cited in the references to this appendix.

These guidelines are cited throughout applicable areas of the text. Please see the following chapters:

- Chapter 134, Cervical Conization
- Chapter 137, Coloscopic Examination
- Chapter 138, Cryotherapy of the Cervix
- Chapter 142, Human Papillomavirus DNA Typing

# BUYING MAJOR OFFICE EQUIPMENT

Mark Needham • Bernard Katz

Throughout their careers, family physicians will be confronted with financial decisions that involve the investment of money with the hope for a profitable return. Buying a major piece of office equipment for a new diagnostic or therapeutic service is one example. Certain decisions, such as paying for office maintenance, are relatively straightforward. If the office isn't maintained properly or the roof leaks, the practice obviously will do poorly. However, buying some office equipment is optional and requires investing money in a piece of equipment now with hopes of earning profit in the future. Certain financial tools, in particular the *calculation of the net present value*, can greatly increase the ability to determine whether to invest in the office equipment and how much to pay for it. This appendix explains how to estimate the value of a piece of office equipment over time so that you can make the right buying decisions.

If a physician has a very strong desire to offer a certain procedure for personal or career goals, and is not strictly motivated by the financial result, the financial analysis that drives the purchase decision may be less important. However, for the most part, physicians should base their decisions on sound financial principles. In so doing they should receive the best possible financial return for their investment.

Wise use of the tools of financial analysis increases the likelihood of making the correct decision so that the value of future dollars will exceed the value of the dollars invested today.

Presented here is a step-by-step approach that will increase the chances that the purchase will turn out to be financially successful. It is based on a simple Excel spreadsheet that includes all the financial information necessary for you to make an informed decision. To help understand how this is acheived, we will use an example of a practice that is considering whether to buy a bone densitometer (Fig. L-1). Make the following entries as shown in the sample in Figure L-1.

#### **ESTIMATE THE LIFETIME OF THE PROJECT**

All equipment has a finite useful life. Equipment wears out; technology becomes obsolete; spare parts become unavailable; and so on. Estimate how long the equipment under consideration will last and enter those years across the top of your spreadsheet. For the example of buying a bone densitometer (a DEXA unit) we have estimated a useful life of 10 years.

#### FORECAST THE ANNUAL REVENUE

Estimate the number of procedures that will be performed on a daily basis and then scale that up to an annual number of procedures. Base your estimate on what you think will happen during the first year of operation. Later you will estimate what the growth rate in the number of procedures will be. Try to be conservative when you make an estimate. If your project exceeds your forecasts, you will only be pleased, but if your forecast is overly optimistic, the result may be a significant financial loss if time, money, and effort will have been expended on a losing project. In the example it is estimated

that during the first year 220 densitometry procedures will be performed.

#### FORECAST THE ANNUAL EXPENSE

Forecasting the annual expense is more complicated than forecasting revenue but equally important. Take a look at a recent income statement from your practice in order to ascertain all the categories of expense that need to be included and to assist with estimates in each category. There are generally two categories of expenses; those associated with *startup* and those that are *recurring annual expenses*. The recurrent expenses comprise both *fixed* and *variable* expenses. Fixed expenses will be incurred regardless of the number of procedures performed, and variable expenses will be dependent on the number of procedures done during the year.

Startup expenses include installation fees, delivery fees, remodeling or construction that may have to be done to ready the premises, licensing, staff training, and any other one-time expenses associated with getting the machine ready to go. Typical recurring annual expenses will include supplies and materials required to operate the machine, staff labor and benefit expense, repair and maintenance, marketing and advertising if required, travel for training, rent, telephone, data lines, insurance, and any other recurring expense associated with the annual operation of the machine.

#### **CONSIDER THE OPPORTUNITY COST**

It may not be easy to place a value on the opportunity cost but it should be considered. In the example of the densitometry machine you need to know whether it is going to be placed into a vacant/ unused area in the office, will displace some existing program, or requires new construction. Vacant and unused office space offers the best upside opportunity because the space is not currently generating any revenue for the practice. In that case the financial analysis simply compares the financial return from one project against the other. If a new piece of equipment is going to displace an existing program, then one has to consider the revenue lost in displacing that program as part of the ongoing annual expense of the new project. It is important to factor in the lost revenue as an expense to the new project to properly decide if buying the new piece of equipment makes financial sense. If new office space has to be acquired or constructed to make room for the new equipment, then the cost of the new construction has to be included in the annual expense, but one can safely allocate that expense over a long time period and then apportion the expense only during the time period under consideration for this project. In the example of densitometry, the assumption is that the machine will be going into unused space in the office so the opportunity cost is stated as zero dollars.

One must also factor in the opportunity cost of the *physician's* time related to the equipment under consideration. Adding laser or colonoscopy equipment to the practice will ultimately require that the physician spend time performing the procedure. That means when he or she is doing colonoscopy or laser procedures, the

#### Sensitivity analysis

This shows the reduction in net present value if revenue forecasts fall short of the original estimate

90% of forecasted revenue NPV \$ 27,534 80% of forecasted revenue \$ 13,569 **NPV** 70% of forecasted revenue NPV \$ (396)

Figure L-I Example of a spreadsheet that can help determine if purchasing equipment makes fiscal sense for a practice.

physician can't also be seeing patients in the office or otherwise generating revenue. For physician-intense equipment, such as colonoscopes and lasers, you must factor in the physician time expense into the annual expenses. Other office-based procedures, such as densitometry, are performed by a technician and require very little time for the physician to interpret the results. Adding a procedure or service that does not require much time input from the physician, although modest in revenue, may ultimately prove to be a better investment for the practice than adding a procedure that requires a lot of physician labor, even though that procedure may produce more revenue. An exception might be a situation such as a laser procedure in which a technician administers the treatment under supervision of the physician. Under those circumstances physician time must be considered at least for the initial consultation, and the technician cost must be included in the expenses.

It is a good exercise for any practice to determine what the average hourly net income is for each physician in the practice. Once that number is determined you can estimate the average hourly net income for an examination room in the office. It is not a good idea to place machinery in an examination room that ultimately produces net income less than that produced by usual patient care, unless the examination room is underutilized anyway. Similarly, it is not a good idea to have physicians switch to doing procedures that result in an hourly net income that is lower than what they produce through usual patient care. Therefore, certain strategic and career decisions may significantly affect this sort of decision. Just be aware that, because of limited resources, a decision to do one thing will typically result in an inability to do another thing.

# FORECAST THE ANNUAL GROWTH RATE FOR REVENUE AND EXPENSE

Revenue growth depends on the expected increase in number of procedures performed as well as the change in reimbursement per procedure. In the densitometry example it is forecasted that there will be a 3% annual growth rate in number of procedures performed and a 1% growth rate in revenue per procedure performed. If you don't think the growth will be a simple percentage annual increase, but instead might increase rapidly over the first few years and then taper off, then go ahead and manually enter the annual number of procedures forecast to be performed each year.

At the minimum, you should estimate that expenses will increase at a typical inflation rate, maybe 3% to 4%. However, for various reasons, medical expense growth seems to have outpaced inflation in recent years. For the densitometry example we have forecasted an annual growth in expenses of 5%.

#### **ESTIMATE THE TERMINAL VALUE**

Most medical equipment wears out, becomes obsolete, or for some reason has to be replaced after some finite period of time. You may be able to sell the equipment to a used machinery vendor or get some trade-in value if buying a replacement, but often the equipment has minimal value at the end of its useful life. It may be that you will be building some sort of business or revenue stream that might have value to a third party. If you can estimate what the resale value of the equipment or the sale value of the business would be at the end of the term under consideration, then you can add that value to the revenue received during the final year of the project. There are other ways to handle the so-called "terminal value," but for our purposes this method will work well.

#### **ESTIMATE THE RISK OF THE PROJECT**

If you have gotten this far in your financial analysis then you should have a series of net annual income numbers along the bottom of your spreadsheet. That is what would be called the *annual cash flow* 

for the project. The Excel spreadsheet program has an extremely useful function called net present value (NPV) that indicates what the value of those cash flows is right now. When we compute the NPV of those cash flows we can then easily compare the value of the cash flows over time, the NPV, to the cost or purchase price of the piece of equipment under consideration. If the NPV exceeds the purchase price, then the project is likely to be profitable. If the NPV does not meet the purchase price, then the project is a loser. When comparing two possible projects for likelihood of success, the project with the greatest NPV will likely be more financially successful. In calculating the value of the cash flows in today's dollars, the NPV calculation is easily able to compare projects of different duration, projects that may or may not have any residual value at the end of their expected lifetime, and projects with cash flows that vary over time.

In order to compute the NPV in Excel you will need the annual cash flows. To use Excel correctly, create and label a cell called NPV below your annual cash flow line. Next, insert the function called NPV. A dialogue box will appear that asks for "Rate," which will be described next, and "Value 1." Click on the "Value 1" box and then drag the cursor across the annual cash flow line from the beginning to the end of the project. That will enter the annual cash flows into the formula. Ignore "Value 2."

You will also need to insert a number in your spreadsheet called the discount rate. When you open the dialogue box for the NPV function in Excel it is called "Rate." The discount rate is a numerical estimate of the risk of the project. Think of the discount rate as the interest rate you would have to pay an outside investor to invest money in your project. If you were selling Treasury bonds backed by the U.S. government, an investor would not require much of a premium beyond the bonds' interest rate to buy Treasury bonds from you because the payment of the interest and principle is virtually a sure thing. However, if you were buying a piece of office equipment to start a medical service in which you had little experience and there was a great deal of competition in your area providing the same service, then an outside investor might ask for a high interest rate, say 20%, because your chance of success and the investor's chance of being repaid is much less than if Treasury bills were the investment. The riskier the project, the higher the interest rate an investor will require because the failure rate increases and the risk of not being fully repaid increases. Investors require higher potential returns for assuming more risk.

Choosing a high discount rate, reflecting a high-risk venture, will cause the NPV of the future cash flows to be lower, whereas a low discount rate will increase the NPV. There is no ideal or perfect way to choose a discount rate. Using 15% is a reasonable discount rate to start with, adding 5 percentage points if you think the project is high risk, and reducing by 5 percentage points if you think the project is rock solid. By varying the discount rate you can see the rate at which the project breaks even; that is, it returns over time the initial investment in the purchase or startup price of the project. If a discount rate less than 10% is required just to break even, you don't have much room for error on your project. Conversely, if a 30% discount rate still yields a NPV above your startup cost, then you have a project with a greater chance of profitability.

You can find the NPV function on the Excel spreadsheet by going to the menu across the top of the worksheet and finding "Insert." Pull down to "Function" and you will be given a list of possibilities. Choose NPV, or Net Present Value, and you will be shown a dialog box where you enter your chosen discount rate and your estimated annual cash flows. Enter the annual cash flows in the box called "Value 1," and enter your chosen discount rate in the box called "Rate." Percentage is entered as a decimal; for example, a chosen rate of 15% is entered in the "Rate" box as .15. Excel will then return the NPV for you to consider when you click "OK." You can ignore the box called "Value 2."

#### PERFORM A SENSITIVITY ANALYSIS

The next step is to challenge some of your forecasts. In performing a sensitivity analysis, you are going to make your forecasts for growth in annual revenue less optimistic, and your forecasts for expense growth more pessimistic. In making these changes in your forecast observe the effect the changes have on the NPV. The greater the amount that the NPV (i.e., the worth of the project over time) exceeds the cost of doing the project, the more likely that the project will be a financial success for you. Similarly, if the NPV exceeds the cost of doing the project, even when your sensitivity analysis subjects your revenue forecasts to only 60% or 70% of the originally forecasted net income, the more likely that your project will be a financial success. Conversely, if the NPV barely exceeds the cost of the project or the NPV actually drops below the cost of the project with minimal reduction in the net income forecasted, then it becomes more likely that the project will be a financial failure, especially when you factor in any "lost" opportunity cost.

It may be true that certain projects have "value" beyond the NPV. Adding a service line through purchase of new equipment may prevent a competitor from doing the same. By adding a procedure to your practice, you may learn a new skill that will allow you to do something else later that has financial benefits. The addition of a service line or procedure may simply make your practice more interesting and enjoyable. However, although these "intangibles" may have bearing on the final decision, just as the opportunity cost may, the most useful and reliable analytic tool that you can bring to the decision-making table is the NPV. Learning to make a forecast of cash flows for your project, estimating risk, calculating the NPV, and relying on this result to guide your decision to buy office equipment will greatly increase your chance of making the right decision.

Take a look at the dexitometry example. The NPV of the cash flows over the 10 years of the project using a 15% discount rate is \$41,499. That barely exceeds the asking price of the machine, which is \$40,000. Effectively, that means that 10 years of densitometry will result in a profit of \$1,499. That is a paltry return on a \$40,000 investment. You'd be better off buying Treasury bonds and leaving that examination room empty or using it for storage until you find something better to do with it. However, let's say you went back to the salesperson and offered \$28,000 for the machine and the offer was accepted. The expected profit would then increase to \$13,499, which is around a 3% annual return on the \$40,000, still not a great

return but beginning to look more reasonable. You can see how knowing the NPV gives you a much firmer foundation to negotiate. A price of \$40,000 would simply be unacceptable for the machine under these circumstances.

Establishing your demand price and walk-away price for purposes of negotiation is a great use of the NPV. You will be much less likely to overpay for equipment, office space, or any capital asset if you have a good sense of the current value (NPV) of your proposed project. The NPV is also useful when two or more potential projects might be competing in your mind for the same space, financial resources, or staff resources. If you use the same rigorous approach to developing the annual cash flows for each project, and appropriately assign a discount rate to each project based upon a fair estimate of the inherent risk of each project, then you will arrive at two NPVs that can be easily compared. Obviously, forecasts are subjective and subject to bias, but if you are even-handed in preparing your financial analysis, and then subject each project to a sensitivity analysis, you can create a best case, expected case, and worst case scenario for each project and then compare them side by side. This method requires less of a "gut" reaction or "seat of the pants" decision, but you will be far more competent at making financial decisions.

#### CONCLUSION

Just as you might practice suturing on pig's foot, you have to practice NPV estimates by making a spreadsheet and "tinkering" around with the revenue forecasts, the expense forecasts, and the discount rate. In so doing you will get a better understanding of what drives the value in a project, just as you might learn how different suture techniques affect the final appearance of a wound closure. Although your goal in a wound closure is an aesthetically appealing result for your patient, your goal in learning how to calculate the NPV is to win the negotiation with your vendor, your landlord, your banker, your broker, or anybody otherwise trying to take advantage of you in a sale. This may not be what you went to medical school for, but it is a handy skill if you want your practice to be more successful.
